9 CASTLEMITCHELL (CHURCHTOWN) PWS

9.1 Introduction

The objectives of the report are as follows:

- To delineate source protection zones for the Castlemitchell (Churchtown) Public Water Supply borehole.
- To outline the principal hydrogeological characteristics of the surrounding area.
- To assist Kildare County Council in protecting the water supply from contamination.

The protection zones are delineated to help prioritise certain areas around the source in terms of pollution risk to the well. This prioritisation is intended to provide a guide in the planning and regulation of development and human activities. The implications of these protection zones are further outlined in 'Groundwater Protection Schemes' (DELG/EPA/GSI, 1999).

The report forms part of the groundwater protection scheme for the county. The maps produced for the scheme are based largely on mapping techniques which use inferences and judgements based on experience at other sites. As such, the maps cannot claim to be definitively accurate across the whole county covered, and should not be used as the sole basis for site-specific decisions, which will usually require the collection of additional site-specific data.

9.2 Summary of Borehole Details

GSI No.	2619SWW449
Grid reference	S ^{2}6384 ^{1}9572
Townland	Raheenadeeragh/ Churchtown South
Owner	Kildare County Council
Well Type	Borehole
Depth	27m (co. co. records)
Elevation	72.63 m OD (Malin Head)
Pumping water level	8.97 m (measured by GSI personnel 9/5/2002)
Static water level	8.94 m (measured by GSI personnel 9/5/2002)
Normal consumption	~17,600 gals/day (80 m^3d^{-1})
Maximum Abstracted **Minimum Abstracted**	152 m^3 d^{-1} (23/10/1999 Kildare Co. Co. records) 33 m^3 d^{-1} (1/1/2000 Kildare Co. Co. records)
Hours Pumping	16-18 hours per day
Depth of pump	~17 m
Depth-to-rock	>10 m
Diameter	150mm
Treatment	Chlorinated and Raw water tap available
System	Live to mains / No reservoir / submersible pump

Note that two additional borehole supplies occur as part of the Castlemitchell scheme. These are termed the "Housing" and "Quarry" supplies. Locations are presented in Map 8. They are much smaller than the Churchtown supply. They did not form part of the investigations into the Castlemitchell (Churchtown) Source Protection Zones and were not visited by the GSI personnel. However, the potential protection area for each lies within the envelope of the Athy and Castlemitchell protection areas and they have been included within the overall source protection considerations for Athy and Castlemitchell.

9.3 Methodology

9.3.1 Desk Study

Details about the borehole such as depth, date commissioned and abstraction figures were obtained from County Council personnel; geological and hydrogeological information was provided by the GSI.

9.3.2 Site visits and fieldwork

This included the following; an interview with the caretaker 9/5/02, water sampling on July 2002 and drilling of depth to bedrock holes 27th & 28th May 2002. Field mapping walkovers were also carried out to further investigate the subsoil geology, the hydrogeology and vulnerability to contamination.

9.3.3 Assessment

Analysis of the data utilised field studies and previously collected data to delineate protection zones around the source.

9.4 Borehole Location & Site Description

The source is located one kilometre north of the main Athy - Stradbally road (R428) approximately 4 km from Athy. The source comprises a single borehole that pumps water directly into the distribution system, which is approximately 14 km in length. At the time of the GSI site visits the system provided water for approximately 320 people, comprising 76 houses and 11 farms. A manhole cover sits over the borehole which is located next to a small pump house that houses the treatment system and a surge tank. Both the pump house and borehole are located at the roadside. The well head lies within a lined concrete chamber 0.5 m deep.

9.5 Topography, Surface Hydrology and Land Use

The topography in the vicinity of the source is flat or undulating with an altitude lying between 70 and 80 m O.D. The general lie of the landscape is a very gentle dip toward the River Barrow. The highest point in the area stands at 268 m O.D. approximately 5 km south west in the vicinity of Ballintlea. The lowest point in the area is the Barrow river which is about 3.5 km to the east of the supply borehole at an elevation of approximately 54 m OD. Overall topographic gradients are in the order of 0.006.

The River Barrow is the largest surface water feature in the area. The land appears to be free draining with only occasional ditches.

Land use around the source is generally tillage and there are only occasional fields used for pasture. Historically there used to be a brick works in the vicinity of the supply borehole. Within 300 m of the supply borehole there are is a church & graveyard, a school and a number of houses. There are also a few sand/gravel pits in the locality (some disused) and there is a large limestone quarry at Ballyadams, approximately 3.5 km south of the supply borehole.

9.6 Geology

9.6.1 Introduction

This section briefly describes the relevant characteristics of the geological materials that underlie the supply borehole. It provides a framework for the assessment of groundwater flow and source protection zones that will follow in later sections.

Geological information was taken from a desk-based survey of available data, which comprised the following:

- Bedrock Geology 1:100,000 Map Series, Sheet 16, Kildare-Wicklow. Geological Survey of Ireland. (Mc Connell *et al*, 1994)

- Information from geological mapping in the nineteenth century (on record at the GSI).
- Glanville (1997) The quaternary geology of Co. Kildare, map descriptions for relevant 1:25,000 sheets. GSI report.

9.6.2 Bedrock Geology

The Ballyadams Limestone Formation occupies the area around the source. It is generally regarded as being a clean, often karstified and dolomitised limestone. The type locality for this rock type is the Ballyadams quarry in County Laois and is approximately 3.5 km south of the supply borehole.

9.6.3 Subsoil (Quaternary) Geology

The main subsoil categories in the vicinity of the source are till (‘boulder clay’) and sand/gravel. The characteristics of each category are described briefly below:

- ‘Till’ or ‘Boulder clay’ is an unsorted mixture of coarse and fine materials laid down by ice. The till is mapped as moderately permeable subsoil (refer to Section 6 Volume I for further details).
- Sand/gravel is widespread in south Kildare. About 500 m to the south of the supply borehole the subsoils change to sand/gravel. Several quarries (some disused) are mapped in the vicinity of the source. One esker is mapped nearby to the source.
- A depth to bedrock drilling programme was carried out to ascertain the subsoil thicknesses. Two holes in the vicinity of the supply borehole have a depth to bedrock that is greater than 10 m. Further west toward the areas of higher relief in County Laois the depth to bedrock decreases significantly and there are areas of shallow rock and outcrop.

9.7 Groundwater Vulnerability

Groundwater vulnerability is dictated by the nature and thickness of the material overlying the uppermost groundwater ‘target’. The uppermost aquifer at the source is the bedrock. The rock is therefore the target and considerations of groundwater vulnerability concern the permeability of the whole subsoil profile and the depth to bedrock.

The vulnerability is discussed in Section 6 of Volume 1. The permeability of the till is thought to be moderate and the permeability of the sand/gravel is thought to be high. Depth to bedrock varies from being greater than 10 m near the source to less than 1 m to the west of the source. Thus the vulnerability to contamination at the supply borehole is moderate but will become more vulnerable moving away from the source with the most vulnerable areas occupying the high ground in County Laois and the least vulnerable areas occupying the area around the supply borehole.

Depth to rock interpretations are based on the available data cited here. However, depth to rock can vary over a small scale. As such, the vulnerability mapping provided will not be able to anticipate all the natural variation that occurs in an area. The mapping is intended only as a guide to land use planning and hazard surveys, and is not a substitute for site investigation for specific developments. Classifications may change as a result of investigations such as trial hole assessments for on-site domestic wastewater treatment systems. The potential for discrepancies between large scale vulnerability mapping and site-specific data has been anticipated and addressed in the development of groundwater protection responses (site suitability guidelines) for specific hazards. More detail can be found in ‘Groundwater Protection Schemes’ (DELG/EPA/GSI, 1999).

9.8 Hydrogeology

9.8.1 Introduction

This section presents our current understanding of groundwater flow in the area of the source.

Hydrogeological and hydrochemical information for this study was obtained from the following sources:

- GSI files and archival Kildare County Council data.
- Kildare County Council drinking water returns.
- Hydrogeological mapping carried out by GSI on 9th, 10th, 27th & 28th May 2002.
- A drilling programme carried out by GSI to ascertain depth to bedrock and subsoil permeability (4 holes in the vicinity of the source and two particle size analyses).
- A Groundwater Protection Scheme for Co. Laois (Deakin, J. *et al* 2002).

9.8.2 Rainfall, Evaporation and Recharge

The term 'recharge' refers to the amount of water replenishing the groundwater flow system. The recharge rate is generally estimated on an annual basis, and generally assumed to consist of an input (i.e. annual rainfall) less water losses prior to entry into the groundwater system (i.e. annual evapotranspiration and runoff). The estimation of a realistic recharge rate is critical in source protection delineation; along with the rate of abstraction at the source it will dictate the size of the zone of contribution to the source. In areas where point recharge from sinking streams, etc., is discounted, the main parameters involved in recharge rate estimation are annual rainfall, annual evapotranspiration, and annual runoff and are listed as follows:

- *Annual rainfall:* 750 mm.
  Rainfall data for gauging stations around Kilkea (from Fitzgerald, D., Forrestal., F., 1996) are as follows:

Gauging Stations	Grid reference	Elevation OD (m)	Approximate distance & direction from source	Annual precipitation 1961-1990
Athy (Voc.Sh)	S656933	61	6 km south east	746 mm
Kilberry	S663999	61	4 km north east	745 mm
Stradbally G.S.	S570966	91	7 km west	807 mm

  As the borehole is closest (in terms of distance and altitude) to the Kilberry and Athy Gauging stations the precipitation is assumed to be about 750 mm annually. This is supported by the interpreted contour maps of precipitation presented in the "Agroclimatic Atlas of Ireland" (Collins and Cummins, 1996).

- *Annual evapotranspiration losses:* 400 mm. Potential evapotranspiration (P.E.) is estimated to be 425 mm $yr.^{-1}$. Actual evapotranspiration (A.E.) is estimated as 95 % of P.E., to allow for seasonal soil moisture deficits. More local measurements of evapotranspiration are not available.

- *Potential recharge:* 350 mm $yr.^{-1}$. This figure is based on subtracting estimated evapotranspiration losses from average annual rainfall. It represents an estimation of the excess soil moisture available for either vertical downward flow to groundwater or runoff and is commonly referred to as "Effective Rainfall".

- *Annual runoff losses:* ~35 mm. The slopes and the nature of the deposits around the source need to be considered in order to give a representative value for the runoff during rainfall events. The subsoils are thought to be free draining and a representative value for the runoff is estimated to be in the order to 10%.

These calculations are summarised as follows:

Average annual rainfall (R)	750 mm
Estimated P.E.	425 mm
Estimated A.E. (95% of P.E.)	400 mm
Potential Recharge (R – A.E.)	350 mm
Runoff losses (10% of recharge)	35 mm
Estimated Actual Recharge	**315 mm**

9.8.3 Groundwater levels, Flow Directions and Gradients

A GSI well survey was carried out in the 1970's in County Kildare, from which broad estimates of the groundwater levels & directions and gradients can be made. In addition, pumping and static water levels in the supply borehole were measured by GSI staff 9/5/2002 and were 8.97 and 8.94 m below ground level respectively. As can be seen from these two measurements there was virtually no variation between the static and pumping water levels. Note that only 30 minutes was allowed for the water level to recover from the pumping water level before the pump had to be turned on again[1]. However, it is generally the case that up to 90% of the expected recovery in a well is within the first 10 minutes.

Water levels measured by the caretaker between April and November 1999 provide data on the seasonal variation of the water levels. Over that period, the variation was about 3 m, where the minimum recorded water level was 8 m below ground in April 1999 and the maximum water level 11.31 m below ground in November 1999. It is assumed that these are pumping water levels because the caretakers records show that the pump is working for about 16-18 hours a day.

Hydrogeological data for other wells in the vicinity of the supply borehole show that the water levels are generally 8 m-11 m below ground level and that the groundwater flow direction is to the east and southeast. This would support the assumption that the regional flow is toward the River Barrow. The higher ground to the west of the borehole in the areas of Binbawn, Ballyduff and Ballintlea are surface watersheds. They are also assumed to be groundwater divides. Groundwater on the eastern side of the divide flows toward the borehole and eventually discharges to the Barrow.

In the vicinity of the source the water table appears to be above the top of the rock; this would suggest that the groundwater is confined at the source.

Groundwater gradients are estimated from these data to be in the region of 0.002-0.004. These gradients are flatter than the topographic gradients.

9.8.4 Hydrochemistry and Water Quality

Data on trends in water quality are summarised graphically in Figure 9-1. The following key points are identified from the data.

- The water is very hard with a total hardness greater than 350 mg l^{-1} (equivalent $CaCO_3$) and electrical conductivity values of 593-798 μS cm^{-1}. These values are typical of groundwater from limestone rocks. As would be expected pH of the groundwater is generally neutral (a mean of 7.2).
- Nitrate concentrations in available samples from the last 7 years are typically 40-50 mg l^{-1} and, until the year 2000, regularly exceeded the EU Drinking Water Directive maximum admissible concentration of 50 mg l^{-1}. However, it appears from the data that there has been a downward trend since 1995, and none of the 19 available results since December 2000 have exceeded 50 mg l^{-1}.
- Chloride is a constituent of organic wastes and levels higher than 25 mg l^{-1} may indicate significant contamination. Chloride data are generally 30 to 40 mg l^{-1}, suggesting that contamination from organic wastes has occurred. In contrast to nitrates, no decrease in chloride levels is evident.
- Of the six available **raw** water analyses of *E.coli*, a detection of 1 count / 100ml was identified on one occasion in 1997.
- The available nitrates, chloride and bacteriological data suggest that groundwater is being contaminated by organic wastes within the catchment of the source. Given that nitrate levels are dropping while chloride is static, it may be that there are two or more types of hazard contributing to contaminant levels in the source (e.g. domestic wastewater treatment systems, landspreading of organic wastes, landspreading of inorganic fertilisers) and it may be that nitrate loadings from one of these hazards (e.g. inorganic fertilisers) have been decreasing in recent years. There is also a

[1] The water supply system is "live" with no reservoir and a full scale pumping test could not be carried out.

graveyard located within 200 m of the borehole which may be contributing to contaminant levels in the source.

9.8.5 Aquifer Characteristics

The Ballyadams limestone is the main aquifer feeding the supply borehole, consisting of thick-bedded clean limestones. On the basis primarily of lithological, karst, and productivity data, this aquifer has been classed as a **regionally important karst aquifer**, with some development potential (**Rk^d**). Further details can be found in Section 4 of Volume I. The available range of values is given in Table 7. The transmissivity estimate was taken from pump testing data of the Fermoyle source in County Laois. In practice, a wide range of transmissivity and permeability values is likely, reflecting the nature of karstified and dolomitised limestones and the unpredictable nature of groundwater flow in these rocks. Faults and fractures are likely to be the focus of groundwater movement and dissolution of the clean limestone is likely to occur preferentially along them.

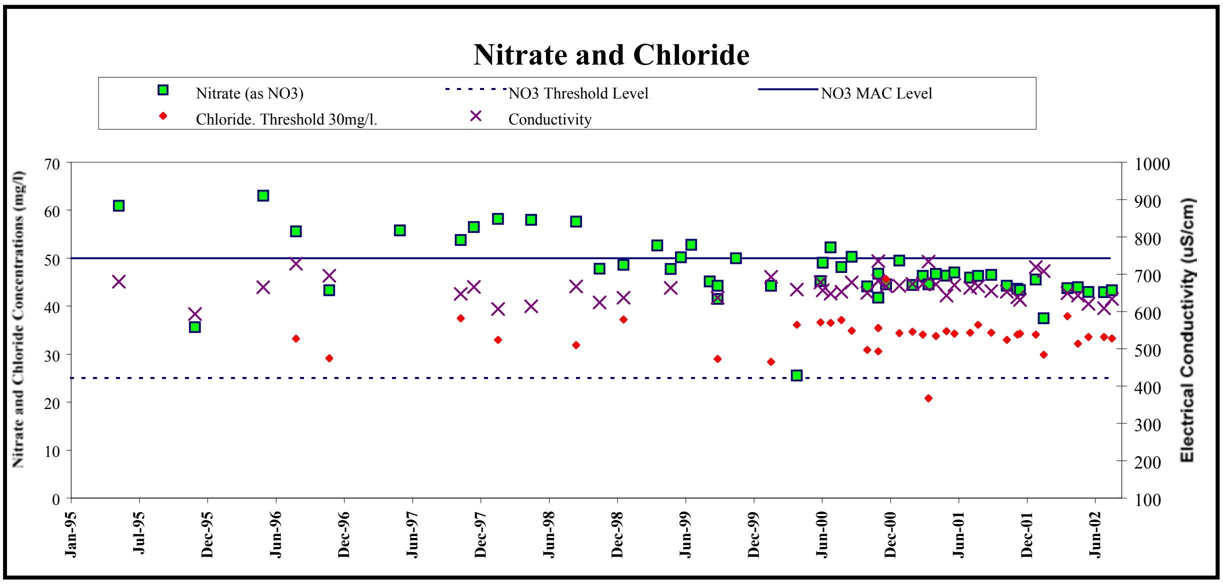
Table 7 Estimated Aquifer parameters for the Ballyadams Limestone at Castlemitchell Supply.

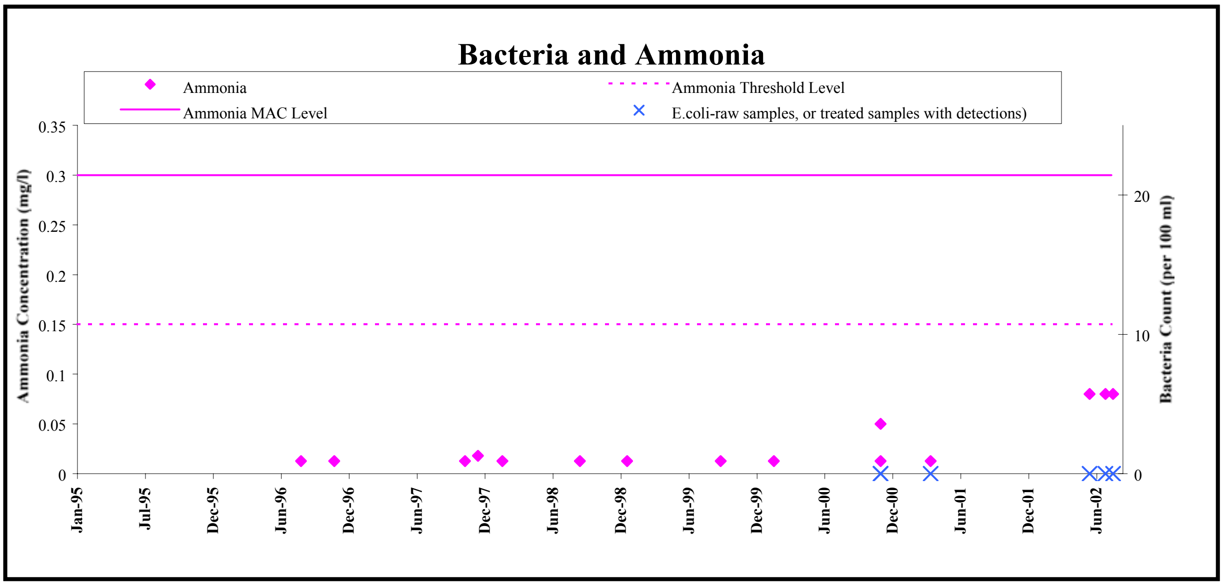
Parameter	*Source of data*	*Ballyadams*
Transmissivity ($m^2 d^{-1}$)	Regional (Laois)	300
Permeability ($m d^{-1}$)	Regional (Laois)	15
Porosity	Assumed	0.01

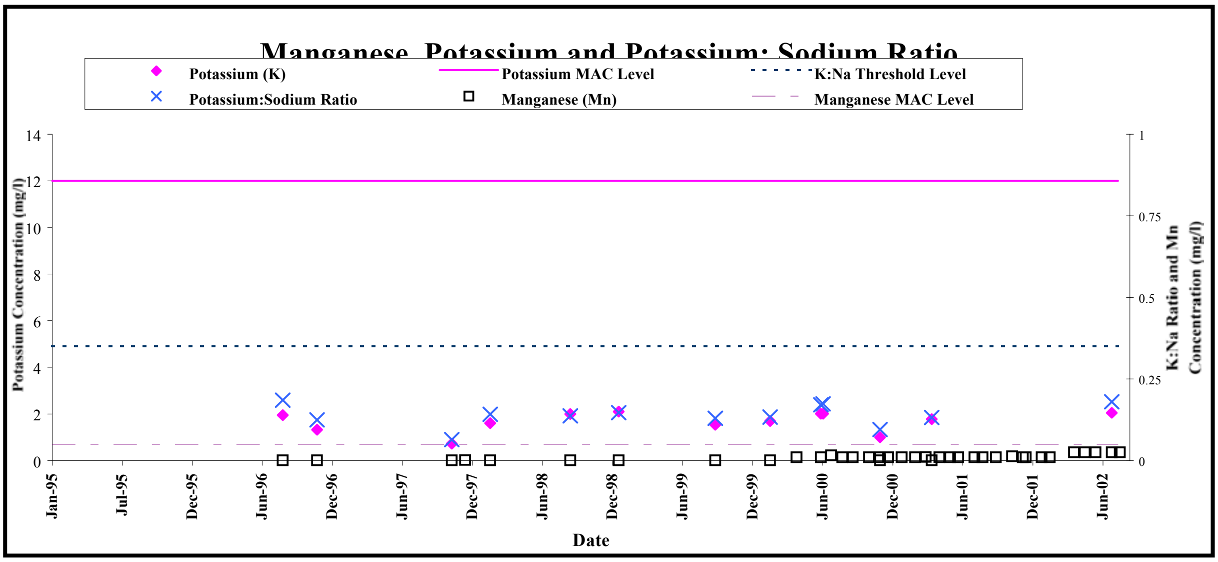
9.9 Conceptual Model

- The Castlemitchell (Churchtown) Public Water Supply borehole is fed by the Ballyadams Limestone Formation which is classed a **regionally important karst aquifer**, with some development potential (**Rk^d**).
- The aquifer parameters in this aquifer are highly variable but are thought to be moderately high in the area of the supply borehole.
- Water levels are generally 8-11 m below ground surface and the bedrock aquifer is confined at the source.
- Groundwater flow is probably confined to fractures, fissures, joints, bedding planes and the uppermost part of the bedrock.
- There are few drains and surface streams and the subsoils are moderately permeable.
- It is thought that the regional groundwater flows to the southeast-east and discharges to the River Barrow.
- Diffuse recharge occurs over most of the land surface through the permeable till. Estimates are in the order of 315 mm yr^{-1}.

Figure 9-1 Castlemitchell - Key indicators of agricultural and domestic groundwater contamination.







9.10 Delineation of Source Protection Areas

9.10.1 Introduction

This section delineates the areas around the source that are believed to contribute groundwater to it, and that therefore require protection. The areas are delineated based on the conceptualisation of the groundwater flow pattern, and are presented in.

Two source protection areas are delineated:

- ♦ Inner Protection Area (SI), designed to give protection from microbial pollution;
- ♦ Outer Protection Area (SO), encompassing the zone of contribution (ZOC) to the borehole.

9.10.2 Outer Protection Area

The Outer Protection Area (SO) is bounded by the complete catchment area to the source, i.e. **the zone of contribution (ZOC)**, which is defined as the area required to support an abstraction from long-term recharge. The ZOC is controlled primarily by (a) the pumping rate, (b) the groundwater flow direction and gradient, (c) the subsoil and rock permeability and (d) the recharge in the area. The ZOC is delineated using both analytical modelling and the results of hydrogeological mapping and conceptualisation. The resulting boundaries are presented in Map 8 and are described as follows:

The **western boundary** is defined using the topographic ridges in Binbawn, Ballyduff, and Ballintlea; all of which are located in County Laois. These ridges are surface watersheds and are assumed to be groundwater divides. As the bedrock is a regionally important karstified aquifer that has high transmissivities it is possible that groundwater flowing from the divide could reach the supply borehole even though the divide is almost five kilometres distant. No significant divides occur closer to the source.

The **eastern boundary** is on the downgradient side of the borehole. Given the flat topography, the generally high bulk permeability in the karst limestone aquifer, and the unpredictable nature of flows in this aquifer, it is considered reasonable to extend the downgradient boundary to 300m, which is the width of the inner source protection area (refer to Section 9.10.3).

The **northern** and **southern boundaries:** these boundaries are complicated by potential interactions with the ZOC for the Athy sources (refer to Section 8.12.2). They are also difficult to determine given the generally flat topography and the karstified nature of the bedrock. Consequently, the ZOC needs to be big enough to incorporate the catchments of several sources and significant safety margins are required to allow for the variability of groundwater flow within bedrock aquifers. The proposed boundaries have therefore been extended to incorporate the most significant topographic hills in the plains area whilst allowing for a significant safety margin.

Note that the area delineated by these boundaries is significantly greater than the area required to supply sufficient diffuse recharge to meet the abstraction demand at the various supply sources. However, given the uncertainties outlined above, it is difficult to justify boundaries which delineate a smaller area.

9.10.3 Inner Protection Area

According to "Groundwater Protection Schemes" (DELG/EPA/GSI, 1999), delineation of an Inner Protection Area is required to protect the source from microbial and viral contamination and it is based on the 100-day time of travel (ToT) to the supply. Estimations of the extent of this area cannot be made by hydrogeological mapping and conceptualisation methods alone. Due to the karstified nature of the limestone aquifer, it is probable that a large proportion of groundwater in the ZOC can travel to the public supply well in less than 100 days. (While this conclusion is arguable, it is advisable to take the precautionary approach in view of the uncertainties concerning flow in karstic limestones.)

Using a permeability value of 15 m d^{-1}, porosity of 0.01 and pumping gradients estimated using the Theim equation, the 100 day ToT is estimated from Darcy's Law to be approximately 300 m for the source.

Given the generally high permeability, gradients should not be significantly influenced by pumping rate and, though they are significantly smaller sources, the inner protection areas for the "Housing" and "Quarry" boreholes are also taken to be 300m.

Inner protection areas for all three supplies are presented in Map 8.

9.11 Groundwater Protection Zones

The groundwater protection zones are obtained by integrating the two elements of land surface zoning (source protection areas and vulnerability categories) – a possible total of 8 source protection zones. In practice, the source protection zones are obtained by superimposing the vulnerability map on the source protection area map. Each zone is represented by a code e.g. **SI/H**, which represents an Inner Protection area where the groundwater is highly vulnerable to contamination.

Four groundwater protection zones are present around the source. The final groundwater protection zones are shown in Map 8. The matrix of source protection zones is given in Table 8. The vulnerability ratings for County Laois are take directly from the Laois Groundwater Protection Scheme (Deakin, J. *et al*, 2002). Due to shallow rock and outcrop in the western part of the source protection area these areas are extremely and highly vulnerable to contamination.

Table 8 Matrix of Source Protection Zones at Castlemitchell.

VULNERABILITY RATING	SOURCE PROTECTION	
	Inner	*Outer*
Extreme (E)	Not present	**SO/E**
High (H)	Not present	**SO/H**
Moderate (M)	**SI/M**	**SO/M**
Low (L)	Not present	Not present

9.12 Potential Pollution Sources

Agriculture is the principal activity in the area. Most of the land is used for tillage, although a small proportion is used for pasture. Potential hazards include farmyards, septic tank systems, application of fertilisers (organic and inorganic), pesticides, and possible spillages along the roads. No door to door survey of specific hazards was carried out as part of this study. The available nitrates, chloride and bacteriological data suggest that groundwater is being contaminated by organic wastes within the catchment of the source. Given that nitrate levels are dropping while chloride is static, it may be that there are two or more types of hazard contributing to contaminant levels in the source (e.g. domestic wastewater treatment systems, landspreading of organic wastes, landspreading of inorganic fertilisers) and it may be that nitrate loadings from one of these hazards (e.g. inorganic fertilisers) have been decreasing in recent years.

9.13 Conclusions and Recommendations

- The source comprises a small production borehole abstracting about 80 m^3 d^{-1} which is located in a **regionally important** karst aquifer, that has some development potential (**Rk^d**).

- The source varies from being moderately vulnerable to contamination near the borehole to extremely vulnerable at the western part of the outer protection area.

- Septic tank systems, farmyards, landspreading of organic and inorganic wastes, the graveyard and runoff from the roads are the main potential hazards in the area.

- The protection zones delineated in the report are based on our current understanding of groundwater conditions and on the available data. Additional data obtained in the future may indicate that amendments to the boundaries are necessary.

- It is recommended that:
  1. the potential hazards in the ZOC should be located and assessed.
  2. a full chemical and bacteriological analysis of the **raw** water is carried out on a regular basis.
  3. particular care should be taken when assessing the location of any activities or developments which might cause contamination at the well, particularly in relation to nitrates.
  4. a full scale pumping test be carried out to estimate the yield of the well and to improve the hydrogeological understanding of the area.

Appendix IV: Discussion Of the Key Indicators of Domestic and Agricultural Contamination of Groundwater

A.1 Introduction

This appendix is adapted from Daly, 1996.

There has been a tendency in analysing groundwater samples to test for a limited number of constituents. A "full" or "complete" analysis, which includes all the major anions and cations, is generally recommended for routine monitoring and for assessing pollution incidents. This enables (i) a check on the reliability of the analysis (by doing an ionic balance), (ii) a proper assessment of the water chemistry and quality and (iii) a possible indication of the source of contamination. A listing of recommended and optional parameters are given in Table A1. It is also important that the water samples taken for analysis have not been chlorinated - this is a difficulty in some local authority areas where water take-off points prior to chlorination have not been installed.

The following parameters are good contamination indicators: E.coli, nitrate, ammonia, potassium, chloride, iron, manganese and trace organics.

TABLE A1

Recommended Parameters		
Appearance	Calcium (Ca)	Nitrate ($N0_3$)*
Sediment	Magnesium (Mg)	Ammonia ($NH_4$and NH_3)*
pH (lab)	Sodium (Na)	Iron (Fe)*
Electrical Conductivity (EC)*	Potassium (K)*	Manganese (Mn)*
Total Hardness	Chloride Cl)*	
General coliform	Sulphate ($S0_4$)*	
E. coli *	Alkalinity	
Optional Parameters (depending on local circumstances or reasons for sampling)		
Fluoride (F)	Fatty acids *	Zinc (Zn)
Orthophosphate	Trace organics *	Copper (Cu)
Nitrite ($N0_2$)*	TOC *	Lead (Pb)
B.O.D.*	Boron (B) *	Other metals
Dissolved Oxygen *	Cadmium (Cd)	
*** good indicators of contamination**		

A.2 Faecal Bacteria and Viruses

E. coli is the parameter tested as an indicator of the presence of faecal bacteria and perhaps viruses; constituents which pose a significant risk to human health. The most common health problem arising from the presence of faecal bacteria in groundwater is diarrhoea, but typhoid fever, infectious hepatitis and gastrointestinal infections can also occur. Although E. coli bacteria are an excellent indicator of pollution, they can come from different sources - septic tank effluent, farmyard waste, landfill sites, birds. The faecal coliform : faecal streptococci ratio has been suggested as a tentative indicator to distinguish between animal and human waste sources (Henry *et al*., 1987). However, researchers in Virginia Tech (Reneau, 1996) cautioned against the use of this technique.

Viruses are a particular cause for concern as they survive longer in groundwater than indicator bacteria (Gerba and Bitton, 1984).

The published data on elimination of bacteria and viruses in groundwater has been compiled by Pekdeger and Matthess (1983), who show that in different investigations 99.9% elimination of *E. coli* occurred after 10-15 days. The mean of the evaluated investigations was 25 days. They show that 99.9% elimination of various viruses occurred after 16-120 days, with a mean of 35 days for Polio-, Hepatitis, and Enteroviruses. According to Armon and Kott (1994), pathogenic bacteria can survive for more than ten days under adverse conditions and up to 100 days under favourable conditions; entertoviruses can survive from about 25 days up to 170 days in soils.

Bacteria can move considerable distances in the subsurface, given the right conditions. In a sand and gravel aquifer, coliform bacteria were isolated 100 ft from the source 35 hours after the sewage was introduced (as reported in Hagedorn et al., 1981). They can travel several kilometres in karstic aquifers. In Ireland, research at Sligo RTC involved examining in detail the impact of septic tank systems at three locations with different site conditions (Henry, 1990; summarised in Daly, Thorn and Henry, 1993). Piezometers were installed down-gradient; the distances of the furthest piezometers were 8 m,10 m and 9.5 m, respectively. Unsurprisingly, high faecal bacteria counts were obtained in the piezometers at the two sites with soakage pits, one with limestone bedrock at a shallow depth where the highest count (max. 14 000 cfu's per 1000 ml) and the second where sand/gravel over limestone was present (max 3 000 cfu's per 100 ml). At the third site, a percolation area was installed at 1.0 m b.g.l; the subsoils between the percolation pipes and the fractured bedrock consisted of 1.5 m sandy loam over 3.5 m of poorly sorted gravel; the water table was 3.5 b.g.l. (So this site would satisfy the water table and depth to rock requirements of S.R.6:1991, and most likely the percolation test requirement.) Yet, the maximum faecal coliform bacteria count was 300 cfus per 100 ml. Faecal streptocci were present in all three piezometers. It is highly likely that wells located 30 m down gradient of the drainage fields would be polluted by faecal bacteria.

As viruses are smaller than bacteria, they are not readily filtered out as effluent moves through the ground. The main means of attenuation is by adsorption on clay particles. Viruses can travel considerable distances underground, depths as great as 67 m and horizontal migrations as far as 400 m have been reported (as reported in US EPA, 1987). The possible presence of viruses in groundwater as a result of pollution by septic tank systems is a matter of concern because of their mobility and the fact that indicator bacteria such faecal coliforms have been found not to correlate with the presence of viruses in groundwater samples (US EPA, 1987).

The natural environment, in particular the soils and subsoils, can be effective in removing bacteria and viruses by predation, filtration and absorption. There are two high risk situations: (i) where permeable sands and gravels with a shallow water table are present; and (ii) where fractured rock, particularly limestone, is present close to the ground surface. The presence of clayey gravels, tills, and peat will, in many instances, hinder the vertical migration of microbes, although preferential flow paths, such as cracks in clayey materials, can allow rapid movement and bypassing of the subsoil.

A.3 Nitrate

Nitrate is one of the most common contaminants identified in groundwater and increasing concentrations have been recorded in many developed countries. The consumption of nitrate rich water by young children may give rise to a condition known as methaemoglobinaemia (blue baby syndrome). The formation of carcinogenic nitrosamines is also a possible health hazard and epidemiological studies have indicated a positive correlation between nitrate consumption in drinking water and the incidence of gastric cancer. However, the correlation is not proven according to some experts (Wild and Cameron, 1980). The EC MAC for drinking water is 50mg/l.

The nitrate ion is not adsorbed on clay or organic matter. It is highly mobile and under wet conditions is easily leached out of the rooting zone and through soil and permeable subsoil. As the normal concentrations in uncontaminated groundwater is low (less than 5 mg/l), nitrate can be a good indicator of contamination by fertilisers and waste organic matter.

In the past there has been a tendency in Ireland to assume that the presence of high nitrates in well water indicated an impact by inorganic fertilisers. This assumption has frequently been wrong, as examination of other constituents in the water showed that organic wastes - usually farmyard waste, probably soiled water - were the source. The nitrate concentrations in wells with a low abstraction rate - domestic and farm wells - can readily be influenced by soiled water seeping underground in the vicinity of the farmyard or from the spraying of soiled water on adjoining land. Even septic tank effluent can raise the nitrate levels; if a septic tank system is in the zone of contribution of a well, a four-fold dilution of the nitrogen in the effluent is needed to bring the concentration of nitrate below the EU MAC (as the EU limit is 50 mg/l as NO_3 or 11.3 mg/l as N and assuming that the N concentration in septic tank effluent is 45 mg/l).

The recently produced draft county reports by the EPA on nitrate in groundwater show high levels of nitrate in a significant number of public and group scheme supplies, particularly in south and southern counties and in counties with intensive agriculture, such as Carlow and Louth. This suggest that diffuse sources – landspreading of fertilisers – is having an impact on groundwater.

In assessing regional groundwater quality and, in particular the nitrate levels in groundwater, it is important that:

(i) conclusions should not be drawn using data only from private wells, which are frequently located near potential point pollution sources and from which only a small quantity of groundwater is abstracted;

(ii) account should be taken of the complete chemistry of the sample and not just nitrate, as well as the presence of *E. coli.*;

(iii) account should be taken of not only the land-use in the area but also the location of point pollution sources;

(iv) account should be taken of the regional hydrogeology and the relationship of this to the well itself. For instance, shallow wells generally show higher nitrate concentrations than deeper wells, low permeability sediments can cause denitrification, knowledge on the groundwater flow direction is needed to assess the influence of land-use.

A.4 Ammonia

Ammonia has a low mobility in soil and subsoil and its presence at concentrations greater than 0.1 mg/l in groundwater indicates a nearby waste source and/or vulnerable conditions. The EU MAC is 0.3 mg/l.

A.5 Potassium

Potassium (K) is relatively immobile in soil and subsoil. Consequently the spreading of manure, slurry and inorganic fertilisers is unlikely to significantly increase the potassium concentrations in groundwater. In most areas in Ireland, the background potassium levels in groundwater are less than 3.0 mg/l. Higher concentrations are found occasionally where the rock contains potassium e.g. certain granites and sandstones. The background potassium:sodium ratio in most Irish groundwaters is less than 0.4 and often 0.3. The K:Na ratio of soiled water and other wastes derived from plant organic matter is considerably greater than 0.4, whereas the ratio in septic tank effluent is less than 0.2. Consequently a K:Na ratio greater than 0.4 can be used to indicate contamination by plant organic matter - usually in farmyards, occasionally landfill sites (from the breakdown of paper). However, a K:Na ratio lower than 0.4 does not indicate that farmyard wastes are **not** the source of contamination (or that a septic tank is the cause), as K is less mobile than Na. (Phosphorus is increasingly a significant pollutant and cause of eutrophication in surface water. It is not a problem in groundwater as it usually is not mobile in soil and subsoil).

A.6 Chloride

The principle source of chloride in uncontaminated groundwater is rainfall and so in any region, depending on the distance from the sea and evapotranspiration, chloride levels in groundwater will be fairly constant. Chloride, like nitrate, is a mobile cation. Also, it is a constituent of organic wastes. Consequently, levels appreciably above background levels (12-15 mg/l in Co. Offaly, for instance) have been taken to indicate contamination by organic wastes such as septic tank systems. While this is probably broadly correct, Sherwood (1991) has pointed out that chloride can also be derived from potassium fertilisers.

A.7 Iron and manganese

Although they are present under natural conditions in groundwater in some areas, they can also be good indicators of contamination by organic wastes. Effluent from the wastes cause deoxygenation in the ground which results in dissolution of iron (Fe) and manganese (Mn) from the soil, subsoil and bedrock into groundwater. With reoxygenation in the well or water supply system the Fe and Mn precipitate. High Mn concentrations can be a good indicator of pollution by silage effluent. However, it can also be caused by other high BOD wastes such as milk, landfill leachate and perhaps soiled water and septic tank effluent.

Box A1 Warning/trigger Levels for Certain Contaminants		
As human activities have had some impact on a high proportion of the groundwater in Ireland, there are few areas where the groundwater is in a pristine, completely natural condition. Consequently, most groundwater is contaminated to some degree although it is usually not polluted. In the view of the GSI, assessments of the degree of contamination of groundwater can be beneficial as an addition to examining whether the water is polluted or not. This type of assessment can indicate where appreciable impacts are occurring. It can act as a warning that either the situation could worsen and so needs regular monitoring and careful land-use planning, or that there may be periods when the source is polluted and poses a risk to human health and as a consequence needs regular monitoring. Consequently, thresholds for certain parameters can be used to help indicate situations where additional monitoring and/or source protection studies and/or hazard surveys may be appropriate to identify or prevent more significant water quality problems.		
Parameter	**Threshold** mg/l	**EU MAC** mg/l
Nitrate	25	50
Potassium	4	12
Chloride	30 (except near sea)	250
Ammonia	0.15	0.3
K/Na ratio	0.3-0.4	
Faecal bacteria	0	0

Box A2 Summary : Assessing a Problem Area

Let us assume that you are examining an area with potential groundwater contamination problems and that you have taken samples in nearby wells. How can the analyses be assessed?

E. coli present ⇨ organic waste source nearby (except in karst areas), usually either a septic tank system or farmyard.
E. coli absent ⇨ either not polluted by organic waste or bacteria have not survived due to attenuation or time of travel to well greater than 100 days.
Nitrate > 25 mg/l ⇨ either inorganic fertiliser or organic waste source; check other parameters.
Ammonia > 0.15 mg/l ⇨ source is nearby organic waste; fertiliser is not an issue.
Potassium (K) > 5.0 mg/l ⇨ source is probably organic waste.
K/Na ratio > 0.4 (0.3, in many areas) ⇨ Farmyard waste rather than septic tank effluent is the source. If < 0.3, no conclusion is possible.
Chloride > 30 mg/l ⇨ organic waste source. However this does not apply in the vicinity of the coast (within 20 km at least).

In conclusion, faecal bacteria, nitrate, ammonia, high K/Na ratio and chloride indicate contamination by organic waste. However, only the high K/Na helps distinguish between septic tank effluent and farmyard wastes. So in many instances, while the analyses can show potential problems, other information is needed to complete the assessment.
