

Environmental Protection Agency

Establishment of Groundwater Source Protection Zones

Carrigbyrne Water Scheme

December 2011

Prepared by:

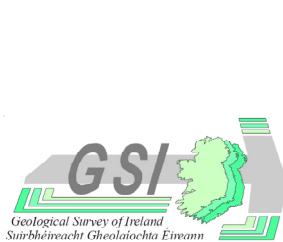

Donal Crean and Sean Moran, OCM

With contributions from:

Dr. Robbie Meehan and Ms. Jenny Deakin

And with assistance from:

Wexford County Council

PROJECT DESCRIPTION

Since the 1980's, the Geological Survey of Ireland (GSI) has undertaken a considerable amount of work developing Groundwater Protection Schemes throughout the country. Groundwater Source Protection Zones are the surface and subsurface areas surrounding a groundwater source, i.e. a well, well field or spring, in which water and contaminants may enter groundwater and move towards the source. Knowledge of where the water is coming from is critical when trying to interpret water quality data at the groundwater source. The Source Protection Zone also provides an area in which to focus further investigation and is an area where protective measures can be introduced to maintain or improve the quality of groundwater.

The project "Establishment of Groundwater Source Protection Zones", led by the Environmental Protection Agency (EPA), represents a continuation of the GSI's work. A CDM/TOBIN/OCM project team has been retained by the EPA to establish Groundwater Source Protection Zones at monitoring points in the EPA's National Groundwater Quality Network.

A suite of maps and digital GIS layers accompany this report and the reports and maps are hosted on the EPA and GSI websites (www.epa.ie; www.gsi.ie).

1 Introduction

Groundwater Source Protection Zones (SPZ) have been delineated for the Carrigbyrne Water Scheme according to the principles and methodologies set out in 'Groundwater Protection Schemes' (DELG/EPA/GSI, 1999) and in the GSI/EPA/IGI Training course on Groundwater SPZ Delineation.

The Carrigbyrne Scheme consists of two boreholes (IE_SE_G_001_26_002) that are approximately 45 m apart. Only one borehole is used at a time to supply the scheme. The boreholes are usually pumped on alternate months.

The objectives of the study were:

- To outline the principal hydrogeological characteristics of the Carrigbyrne area where the supply well is located.
- To delineate source protection zones for the well.
- To assist the Environmental Protection Agency (EPA) and Wexford County Council in protecting the water supply from contamination.

SPZs are intended to provide a guide in the planning and regulation of development and human activities to ensure groundwater quality is protected. More details on SPZ are presented in 'Groundwater Protection Schemes' (DELG/EPA/GSI, 1999).

2 Methodology

The methodology applied to delineate the SPZ consisted of data collection, desk studies, site visits and field mapping and subsequent data analysis and interpretation.

An initial interview with the caretaker of the supply scheme and the field mapping of the study area were undertaken on 16//09/2011.

While specific fieldwork was carried out in the development of this report, the maps produced are based largely on the readily available information and mapping techniques using inferences and judgements from experience at other sites. As such, the maps may not be definitively accurate across the whole area covered, and should not be used as the sole basis for site-specific decisions, which will usually require the collection of additional site-specific data.

3 Location, Site Description and Well Head Protection

The site is approximately 12 km east of New Ross and 21 km west of Wexford Town, in the townland of Scullaboge. The boreholes are 70 m north of the National Road N25 and just south of Carrickbyrne Forest Park.

The site is accessed from a third class road running northwest from the N25. It consists of a hardcore covered laneway approximately 90 m in length with a locked farmyard gate at the site entrance.

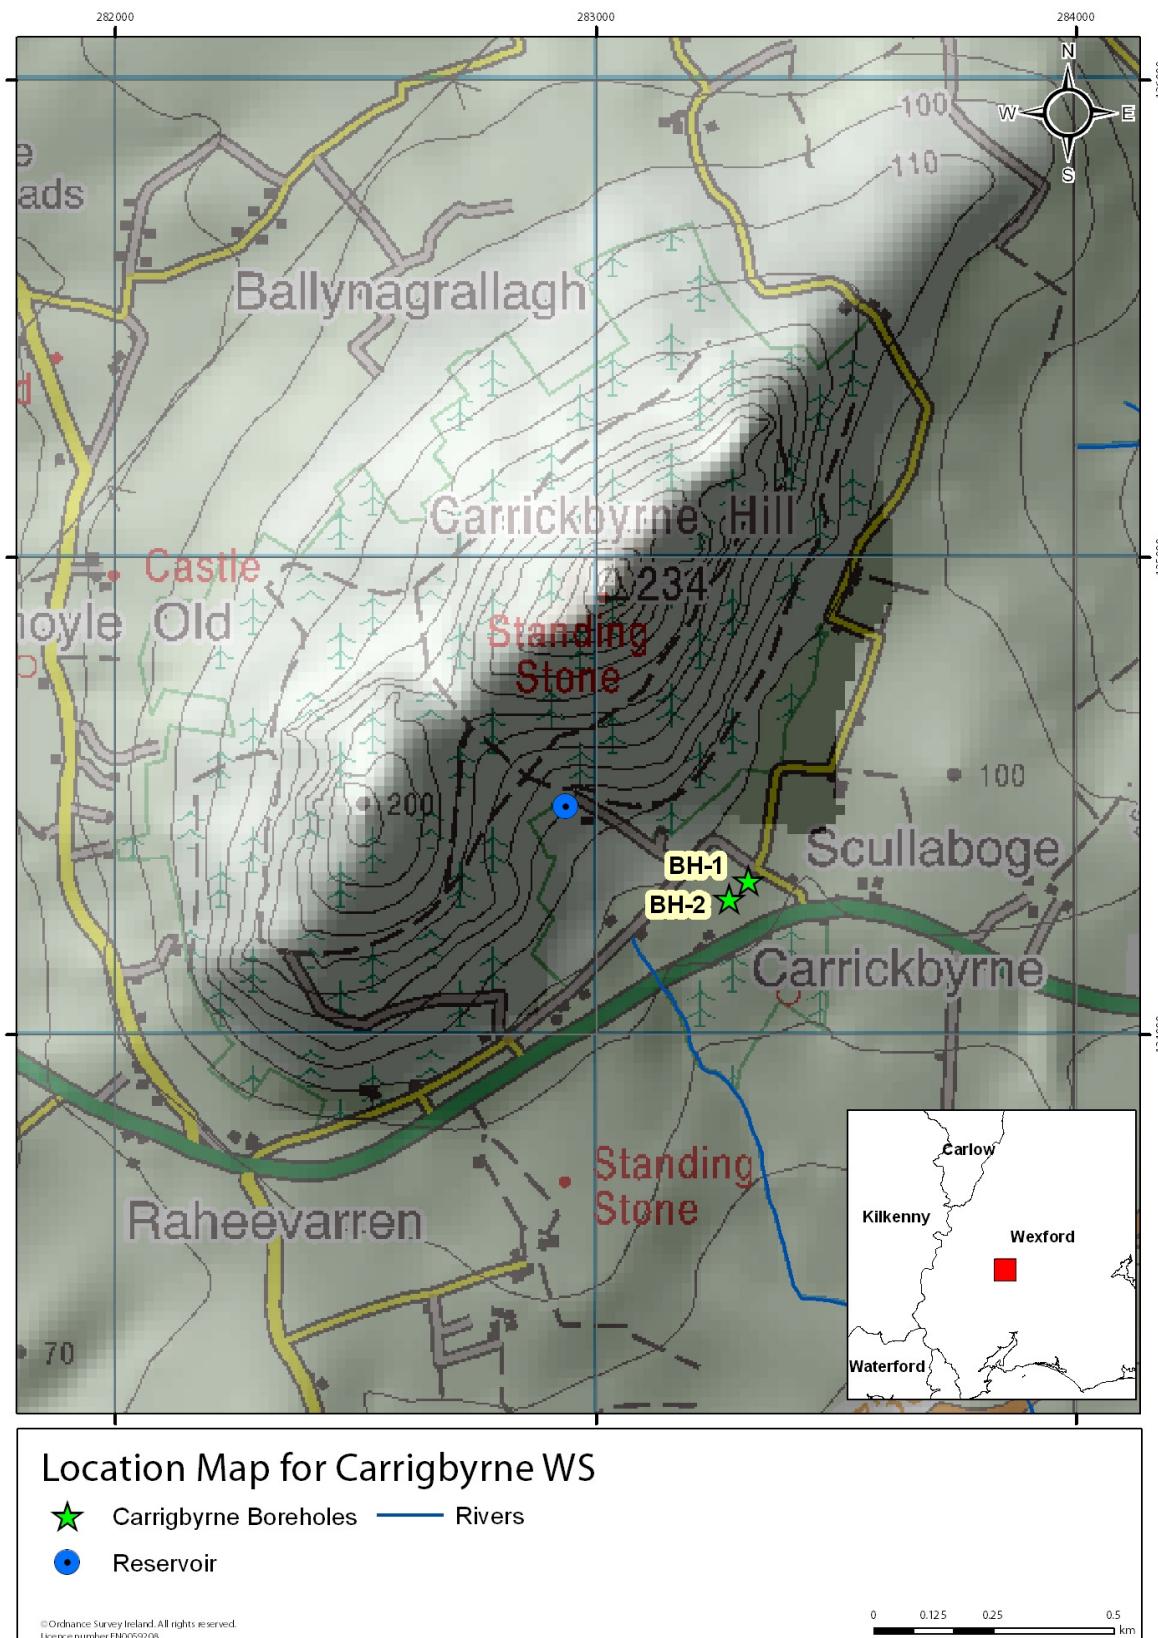

Figure 1: Location Map

There are two abstraction wells (boreholes) at the site with the pump house situated between the boreholes. BH-1 is closest to the site entrance on the eastern side of the pump house and is 30 m from the road. BH-2 is at the western boundary of the laneway, c.90 m from the road (Photo 1). Each well is located in a concrete chamber. The chambers are 2.05 m wide, 1.87 m deep and 0.87 m high with locked steel covers (Photo 2). The chambers were constructed approximately three years ago and replaced temporary steel sheds.

Both wells have had new pumps installed within the last two years. Metal plates were fitted at the well heads to secure the pumps in place at depth in the wells. These plates also prevent debris from falling into the wells (photos 3 and 4).

Photo 3 BH-1

Photo 4 BH-2

4 Summary of Well Details

The boreholes were installed in the mid 1960's as part of a local group water scheme. Wexford County Council took over the scheme in the mid 1970's. There are no borehole records. Based on discussions with the caretaker, it is assumed that the 203 mm casing extends to the bedrock and that the remainder of the boreholes were drilled as open hole. The depth to bedrock is unknown. Before the new pumps were installed the total depths of the wells were measured at approximately 33.5 m (110 ft) in order to site the pumps at an appropriate depth. The pumps were placed at 33.5 m (110 ft) below ground level.

Only one borehole is pumped at a time. The boreholes are switched generally every month. The water is treated by chlorination and with sodium carbonate to correct the pH. The pump in use is activated by a float switch at the reservoir. The water is then pumped, at a rate of 22 m³/hr, to the reservoir for distribution to the network. The maximum total daily abstraction is 410 m³/d (18.6 hours pumping) due to the size of the reservoir. The reservoir is approximately 420 m northwest of the boreholes at the end of a laneway leading to Carrickbyrne Hill (Photo 5).

Information on the pumping regime was gleaned from a three day pumping test which is discussed further in Section 9.2 below. During the pumping test the water level ranged from 18.16 m bgl to 20.13 m bgl although this was during an extended recovery and pumping period. Under normal conditions, pumping lasts between three to five hours until the reservoir is full, depending on demand. This is followed by a recovery period between 0.75 hours and 1.5 hours. The average change in water level under normal conditions is 1.5 m. The temperature rises slightly from 10.78 to 10.92 °C with the rising water level. The pumping regime can be seen on Figure 2 below. This figure indicates that the on-off cycle for the pumping regime is very short and this could shorten the life span of the pumps in the long term.

Table 4-1 provides a summary of the details as currently known.

Table -4-1: Well Details

	BH-1	BH-2
EU Reporting Code		IE_SE_G_001_26_002
National Drinking Water Code		3300PUB1012
Grid ref.	283319, 124322	283278, 124283
Townland		Scullaboge
Source type	Borehole	Borehole
Drilled		1960's
Owner		Wexford County Council
Elevation (Ground Level)		~94 m OD
Depth (m)	Estimated 33.5 m (110 feet)	Estimated 33.5 m (110 feet)
Depth of casing		Unknown but assumed to bedrock
Diameter		203 mm (8 inch) at surface. 4 inch rising main
Depth to rock	Unknown	Unknown
Static water level	Unknown	Unknown
Pumping water level	18.5-20.2 m bgl for yield 22 m ³ /hr	Unknown
Consumption (Co. Co. records)		300-340 m ³ /d
Pumping test summary:		
(i) abstraction rate	22 m ³ /hr (528 m ³ /d)	
(ii) specific capacity	268 m ³ /d/m	
(iii) transmissivity	205-220 m ² /d

5 Topography, Surface Hydrology & Landuse

The borehole is located on the southern footslopes of Carrickbyrne Hill, at approximately 94 m OD. Carrickbyrne Hill is the highest point in the sub-catchment at 234 m OD, and is located 680 m northwest of the source. The land slopes from the hill to the south east, towards a tributary of the Corock River. The topographic gradient from the top of the hill to 110 m OD is steep, at approximately 0.27, before decreasing from this point to the boreholes to c.0.07. The overall gradient is 0.21. There are road gullies along the public roads immediately to the east and north of the site along the break in slope. These drains appear to have been constructed to take rainfall run-off where infiltration is low due to the change from exposed or shallow bedrock to gley soils. There are also drains along the field boundaries in the surrounding lands. In the fields immediately up hydraulic gradient of the site the drains discharge to a local stream tributary of the Corock River situated 220 m west of the site. The tributary flows to the south and joins the Corock approximately 4.6 km southeast of the site. The Corock River flows southwards into Bannow Bay just west of Wellington Bridge approximately 10.8 km south of the site. At the time of the site visit, in October, the upper parts of the tributary were mostly dry with some standing water in places.

Land use in the high ground to the northwest of the site is dominated by mixed conifer and broadleaf forestry. This area is part of the Coillte operated Carrickbyrne Hill amenity walking trail. Details on the trails can be found on <http://www.coillteoutdoors.ie/>. Lower down in the catchment the landuse is grassland for dairy farming. Photo 6 shows the landuse in the low lying land taken from Carrickbyrne Hill. There are 19 no of houses, Cedar Lodge Hotel, a petting farm and a repair and sales garage located within 500m of the site. The dwellings are located along the N-25, the local public road which runs from the N-25 north past the site entrance with one branch of the road heading north and the other to the west. The northern branch ends at one of the entrances to the Coillte Trail.

The car garage is 280 m northwest of the site. The main garage area is concrete paved. The activity appears to be well maintained and there was no evidence of oily run off or staining based on observations of the site activity from the public road. This is however, a potential point source of contamination for hydrocarbons or volatile organic compounds. The reservoir for the Carrigbyrne water supply scheme is located 90 m north of the repair garage. The road which forks to the west reconnects with the N-25 approximately 1.1 km to the west of the site. There are 7 no of dwellings along this road including the petting farm which is approximately 180 m from the site. The Cedar Lodge Hotel is located approximately 270 m east of the boreholes. It is considered to be downgradient of the site.

Photo 6: Landuse seen from Carrickbyrne Hill

6 Hydrometeorology

Establishing groundwater SPZs requires an understanding of general meteorological patterns across the area of interest. Meteorological information was obtained from Met Éireann.

Annual rainfall: 1000 mm. The contoured data map of rainfall in Ireland (Met Éireann website, data averaged from 1961–1990) shows that the source is located close to the 1000 mm average annual rainfall isohyet.

Annual evapotranspiration losses: 499 mm. Average potential evapotranspiration (P.E.) is estimated to be 525 mm/yr based on the contoured data map of potential evapotranspiration in Ireland (Met Éireann website, data averaged from 1971–2000) which shows that the source is located close to the 530 mm average annual evapotranspiration isohyet. Actual evapotranspiration (A.E.) is then estimated as 95% of P.E., to allow for seasonal soil moisture deficits.

Annual Effective Rainfall: 501 mm. The annual average effective rainfall is calculated by subtracting actual evapotranspiration from rainfall. Potential recharge is therefore equivalent to this, or 501 mm/year.

7 Geology

7.1 Introduction

This section briefly describes the relevant characteristics of the geological materials that underlie the site. It provides a framework for the assessment of groundwater flow and delineation of the source protection zones. The desk study data used comprised the following:

- Geology of South Wexford. Bedrock Geology 1 : 100,000 Map series, Sheet 23, Geological Survey of Ireland (D. Tietzsch-Tyler, A.G. Sleeman 1994)
- Forest Inventory and planning system – Integrated Forestry Information System (FIPS-IFS) Soils Parent Material Map, Teagasc (Meehan, 2002).
- Geological Survey of Ireland (2004) 1st Draft Adamstown GWB Description.

7.2 Bedrock geology

The boreholes are drilled into the Campile Formation which is classified as being part of the Ordovician Volcanics Rock Unit Group. This formation comprises rhyolitic volcanic rock and grey & brown slates. There is a change in the bedrock approximately 250m north of the boreholes. The mapped change in bedrock corresponds to a break in the topographic slope. The high ground at Carrickbyrne Hill comprises felsic volcanic bedrock that was intruded into the Campile Formation. The outcrops in the catchment appear to be the felsic intrusions at Carrickbyrne Hill. A typical outcrop is shown on Photo 7. A quarry is located 3.1 km northeast of the site and is mapped in the felsic intrusion (Photo 8).

Northeast of Campile these volcanic rocks occur only as large lenticular bodies which are isolated within a Campile Formation succession dominated by mudstones (Geology of South Wexford). The bedrock Geology is illustrated in Figure 3.

Photo 7: Outcrop on Carrickbyrne Hill

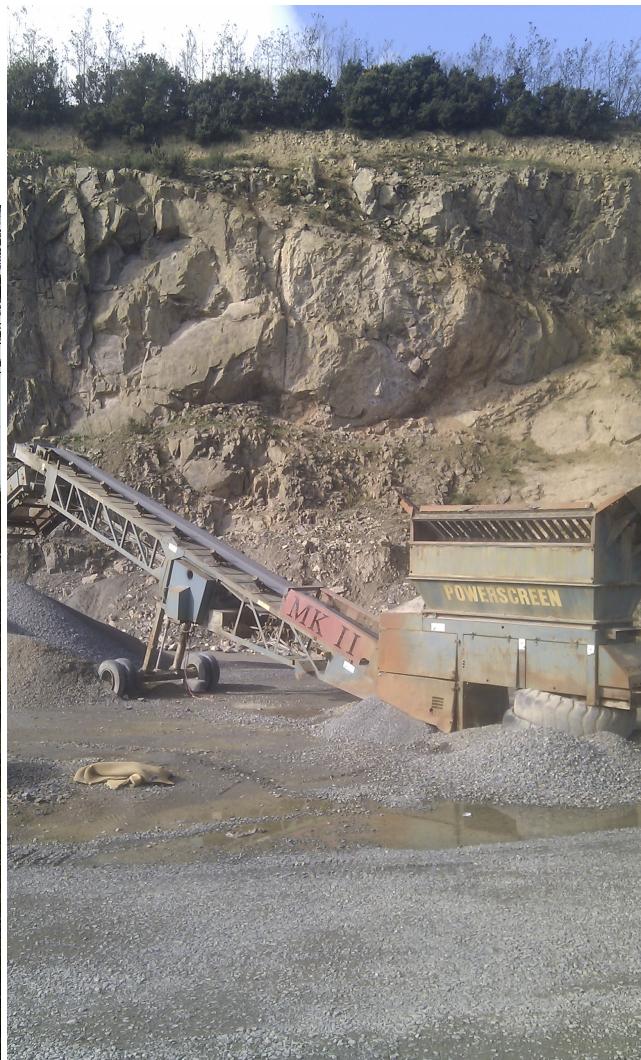

Photo 8: Nearby Quarry

The geological map (GSI Sheet No. 23) indicates that the rocks have been folded and faulted by compression that occurred with the creation of the Caledonian Mountains during the Silurian period. This event is known as the Caledonian Orogeny. The Campile Formation is in the centre of a syncline and is flanked by the older Ordovician Metasediments to the north and south. Either side of the boreholes is a series of north-south trending faults. These are perpendicular to the regional synclinal feature.

The Adamstown Groundwater Body (GWB) description, compiled by the GSI, indicates that Campile Formation in Wexford reacted in a brittle manner to orogenic deformation, allowing the development of a network of fracturing and fracture permeability. This extensive fracturing and faulting has most likely given rise to zones of enhanced permeability in the formation. This is discussed further in Section 9. The GSI GWB Report is included in Appendix 1.

7.3 Soil and Subsoil geology

The soil and subsoil distributions are illustrated in Figures 4 and 5, respectively. According to the EPA and Teagasc Soil and Subsoil mapping, the soil is classified over the high ground (c.110m OD) as Acid Mineral Shallow Well Drained Soil (AminSW) and to the south at lower elevations (c.100 m OD) as Acid Mineral Soil Deep Well Drained soil (AminDW).

The bedrock outcrops above 120 m OD at Carrickbyrne Hill and the hill to the southwest of it. Below 120 m OD, the bedrock is overlain by a Lower Palaeozoic Shale Till (TLPS) derived from the underlying Ordovician bedrock, which appears to increase in thickness moving to the southeast to the boreholes. The subsoil thickness at the borehole is unknown but is estimated to be close to 9 m based on the depth to bedrock of a well located 170 m to the west. Another borehole 450 m to the west, but higher in the catchment, has a depth to rock of 5 m according to its borehole log.

The subsoil is characterised as moderate to low permeability on the GSI vulnerability maps. BS5930 field assessment of the soils in the fields around the boreholes indicated poorly drained CLAY dominated gleys.

7.4 Depth to Bedrock

There are no details for the production boreholes. Depth to rock Information was obtained from two nearby boreholes. Approximately 170 m west of BH-2, the depth to rock is estimated at 9.1 m below ground level (bgl) from a domestic borehole. Further to the west, a hydrogeological assessment was done in 1981 on a borehole for a potential bottled water supply (K.T. Cullen 1981). The depth to bedrock in this well was recorded as being 5 m bgl and is located approximately 540 m west of the production boreholes. The location and depths of these points is shown on Figure 5.

8 Groundwater Vulnerability

Groundwater vulnerability is dictated by the nature and thickness of the material overlying the uppermost groundwater 'target', which in this case is the bedrock aquifer. This means that in this area, the vulnerability relates to the permeability and thickness of the subsoil. A detailed description of the vulnerability categories can be found in the Groundwater Protection Schemes document (DELG/EPA/GSI, 1999) and in the draft GSI Guidelines for Assessment and Mapping of Groundwater Vulnerability to Contamination (Fitzsimons et al, 2003).

The vulnerability map is shown in Figure 6. In terms of subsoil coverage within the catchment of the wells, the area can be divided into two zones:

- Over the high ground to the north and northwest, situated between approximately 120 m OD and the top of the catchment, at Carrickbyrne Hill, the subsoil is very thin or absent. Here the vulnerability is classed as Extreme or Extreme with Rock near the surface. This represents the largest portion of the source catchment (around 80%).
- Over the remainder of the catchment, the vulnerability ranges from high to low. Based on the nature of the soil and subsoil material (Gleys and low permeability subsoil) observed during the site visit, and the depth to bedrock of the nearby domestic well, the vulnerability at the boreholes is considered likely to be low.

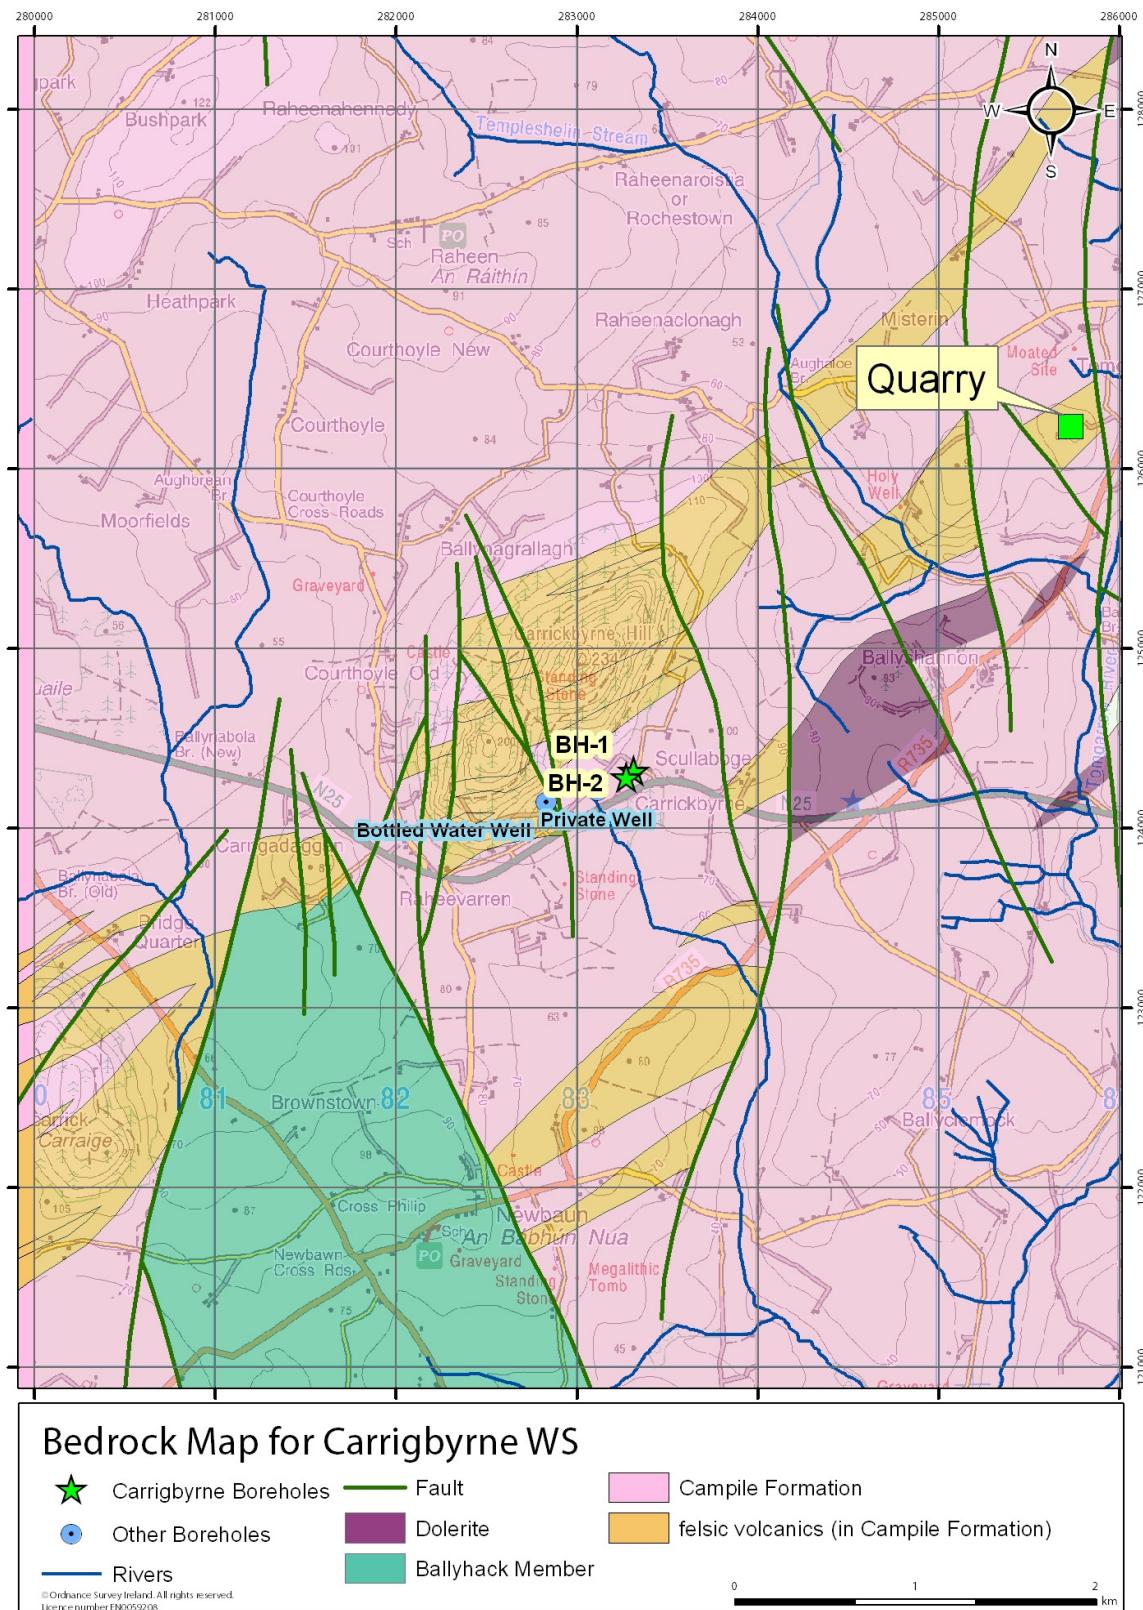

Figure 3: Bedrock Map

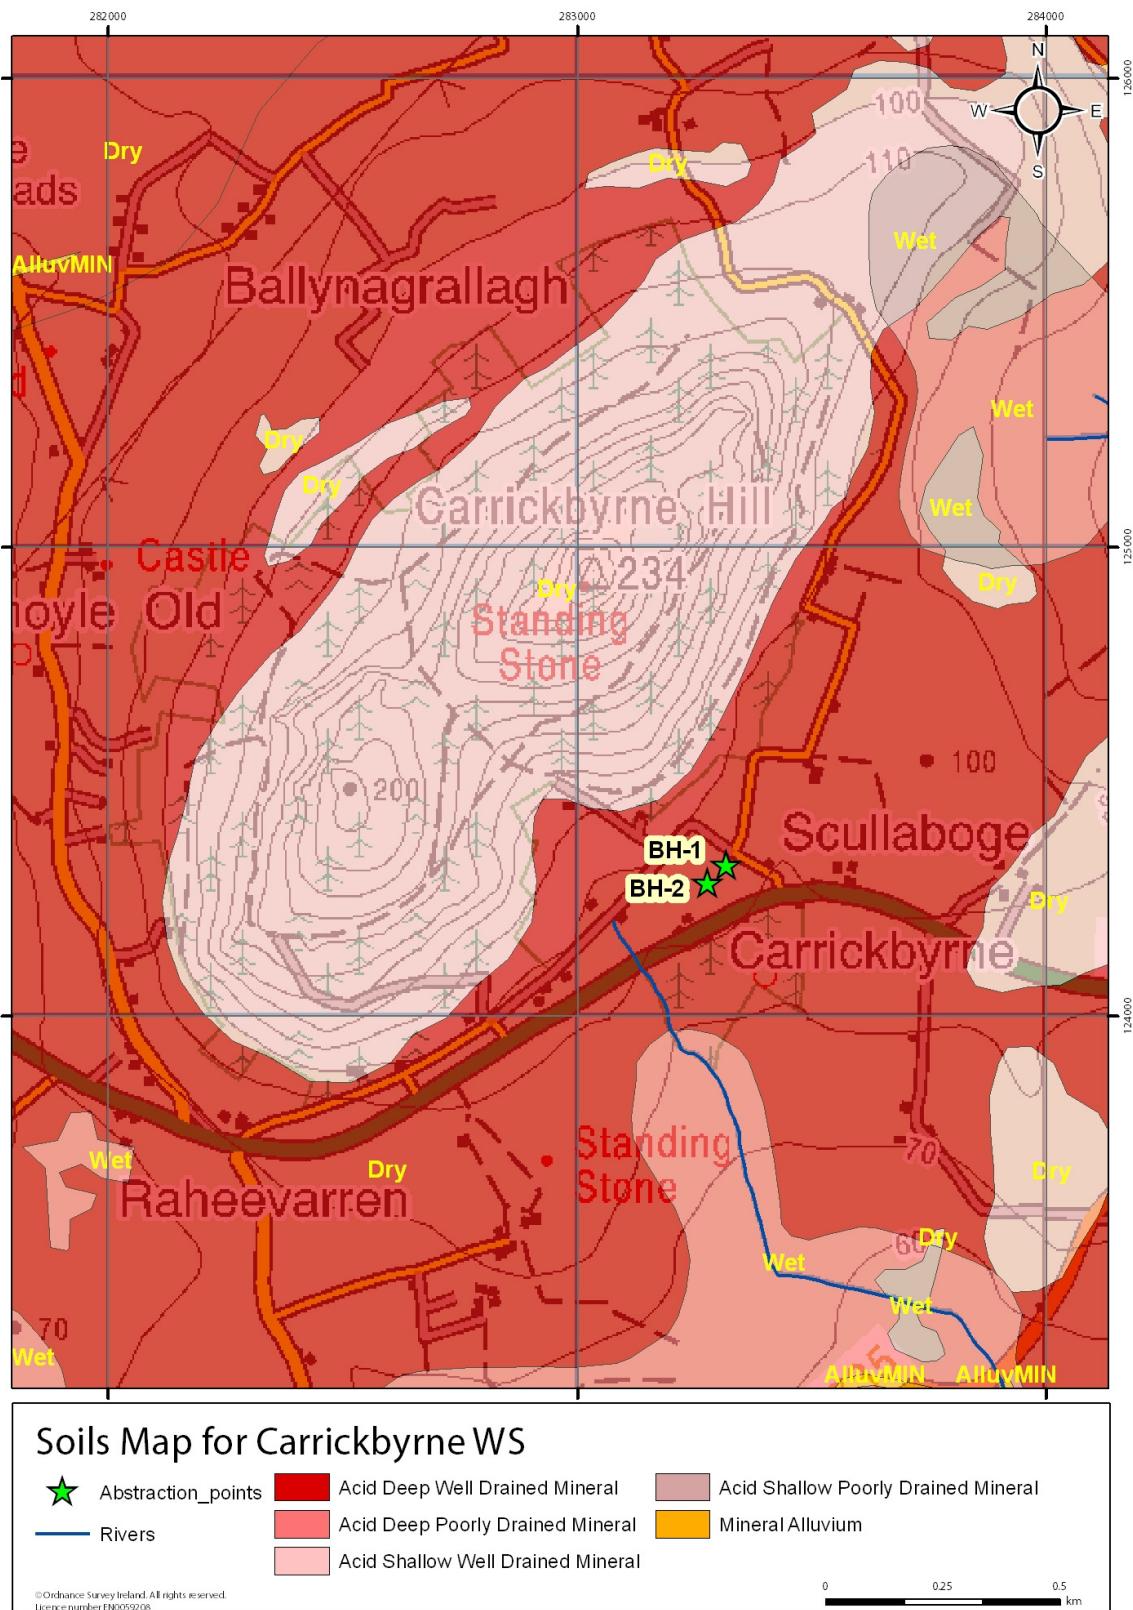

Figure 4: Soils Map

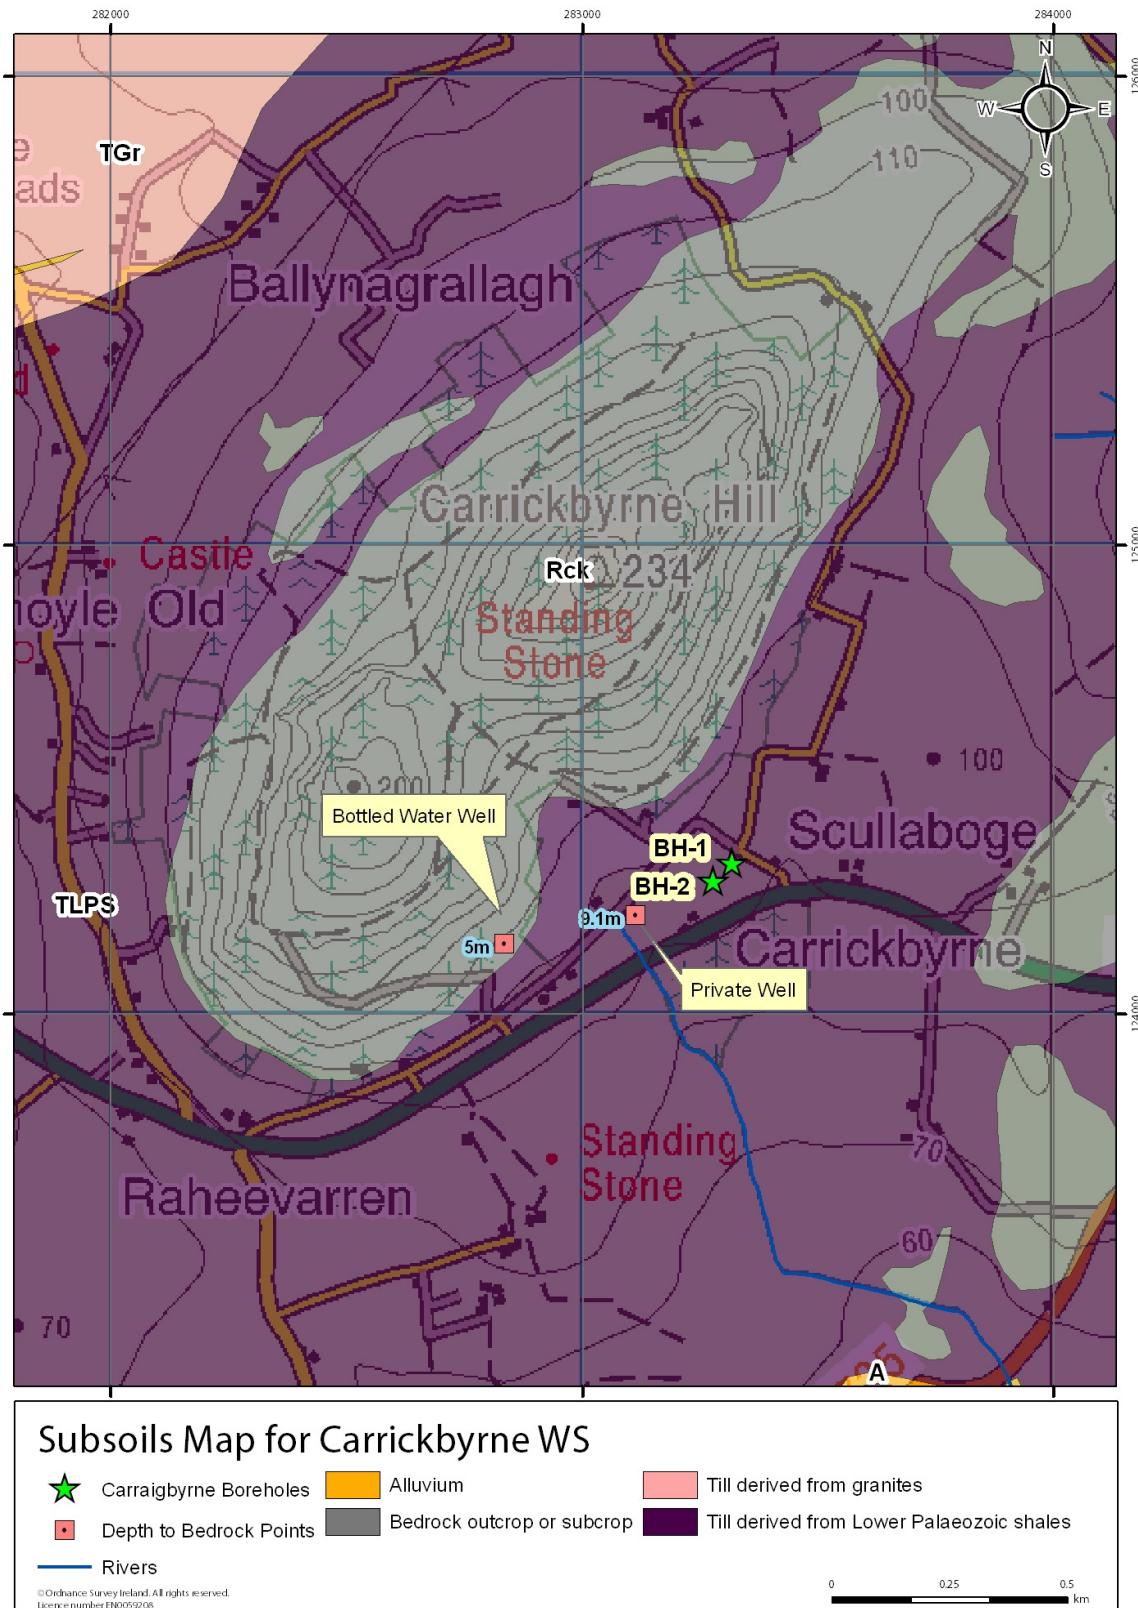

Figure 5: Subsoils Map

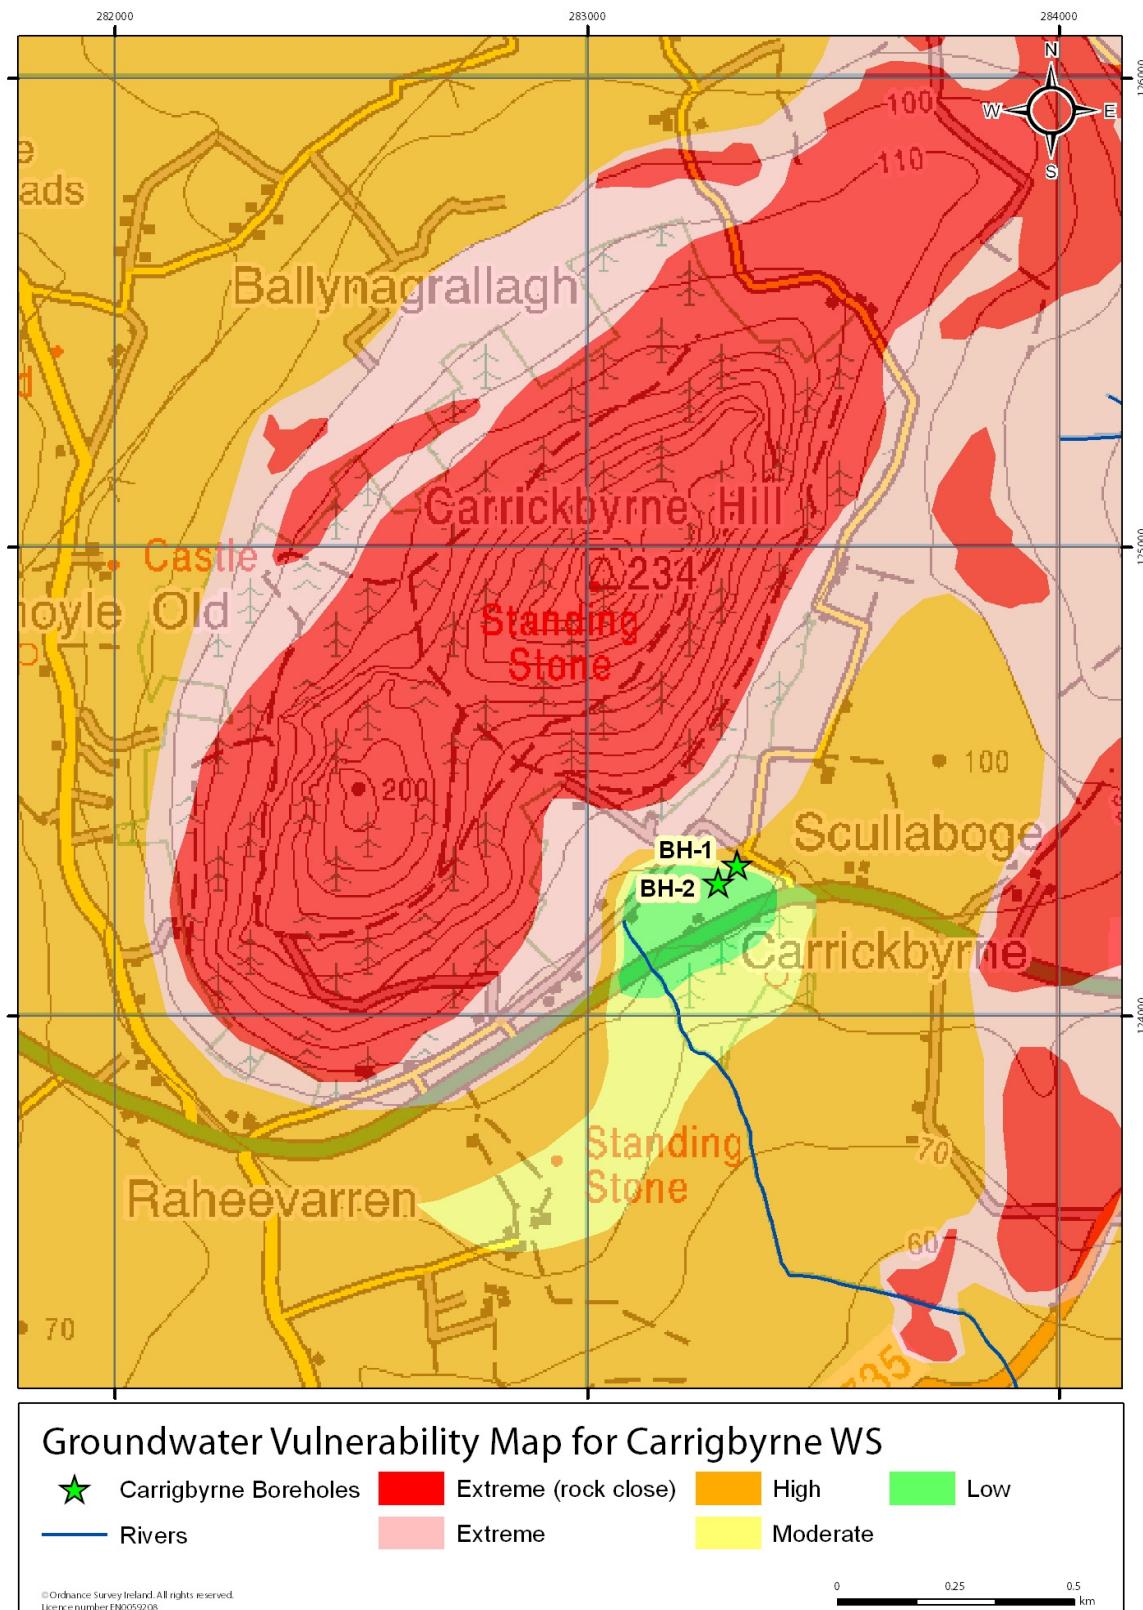

Figure 6: Groundwater Vulnerability Map

9 Hydrogeology

This section describes the current understanding of the hydrogeology in the vicinity of the wells. Hydrogeological and hydrochemical information was obtained from the following sources:

- GSI Website and Database
- County Council Staff
- EPA website and Groundwater Monitoring database
- Local Authority Drinking Water returns
- The Adamstown Groundwater Body initial characterisation report
- Camross Regional Water Supply Scheme Groundwater Investigations (K.T. Cullen 1987)
- Report on the Drilling and Testing of a Trial Well at Carrickbyrne, Co. Wexford (K.T. Cullen 1981)

9.1 Groundwater Body and Status

The boreholes are located within the Adamstown Groundwater Body (IE_SE_G_001) which has been classified as being of Good Status. The groundwater body description is available from the GSI website: www.gsi.ie and is provided in Appendix 1. The 'status' is obtained from the Water Framework Directive website: www.wfdireland.ie/maps.html.

9.2 Groundwater Levels, Flow Directions and Gradients

There are no static water level data available for the wells. A data logger was placed in BH-1 for almost 72 hours to complete a limited pumping test during the supply cycle. The caretaker ensured the reservoir was full before manually switching off the borehole to maximise the initial recovery time. The highest the water level rose to was 18.16 m bgl. This was recorded when the pump was switched off for 177 minutes to undertake the short term recovery test. The lowest level of 20.13 m bgl was recorded when the pump was switched back on again to fill the reservoir after the longer than usual recovery period. During this period BH-1 was pumping for 382.5 minutes (6.22 hours). This was a fluctuation of 2.03 m. Over the remainder of the three day period that the logger was in use, the water level generally fluctuated by c. 1.5 m during the normal on-off pumping cycle.

The closest nearby private borehole could not be dipped. However an attempt was made to dip the test well installed for the Bottled Water project located 500 m to the west. The log for the Bottled Water well indicates it was bored to 51 m bgl. On the day of the site inspection a dip meter could only reach 14.47 m bgl and the well was dry. It is assumed the borehole is blocked. A static water level of 18.05 m bgl was recorded before a pumping test in 1981.

Based on the topography and surface water drainage, groundwater infiltrates mostly directly to the bedrock to the north and northwest of the borehole and flows to the south-east towards the Corock river valley. There is expected to be low recharge to the boreholes from the low lying areas around the borehole due to the low permeability material encountered. The topographic gradient is steep and is estimated at 0.19. Based on the recorded water levels in the above groundwater wells, the groundwater gradient is expected to be shallower. Based on the estimated static water level for BH-1 and the Bottled Water wells located c.500m up hydraulic gradient to the west, the hydraulic gradient is estimated to be 0.08.

9.3 Hydrochemistry and Water Quality

The site has been included in the EPA operational chemical monitoring network since 2003. Raw water sample points are located in each of the borehole chambers. The EPA sample is taken from whichever borehole is being pumped. There is a treated water sample point in the pump house. The laboratory results have been compared to the EU Drinking Water Council Directive 98/83/EC Maximum Admissible Concentrations (MAC) and, where relevant, mean values have been compared to the Threshold Levels in the European Communities Environmental Objectives (Groundwater) Regulations 2010 adopted in Ireland (S.I. No. 9/2010). The EPA data are graphed in Figures 6 to 8 and are summarised below.

- 'The water has a calcium bicarbonate hydrochemical signature and is soft (Average Total Hardness 46 mg/l CaCO₃). The average conductivity is 184 µS/cm. The pH was lower than the MAC range of between 6.5 and 9.5, on 10 occasions from a total of 12 analyses. The average pH is 6.1 which indicates a mildly acidic water, probably related to the siliceous nature of the bedrock. The water is treated for pH in the pump house before going to the reservoir for distribution.
- Faecal Coliforms were detected twice in 20 EPA analyses and not since 2007. Ammonium values were not recorded above the Threshold Level (0.175 mg/l).

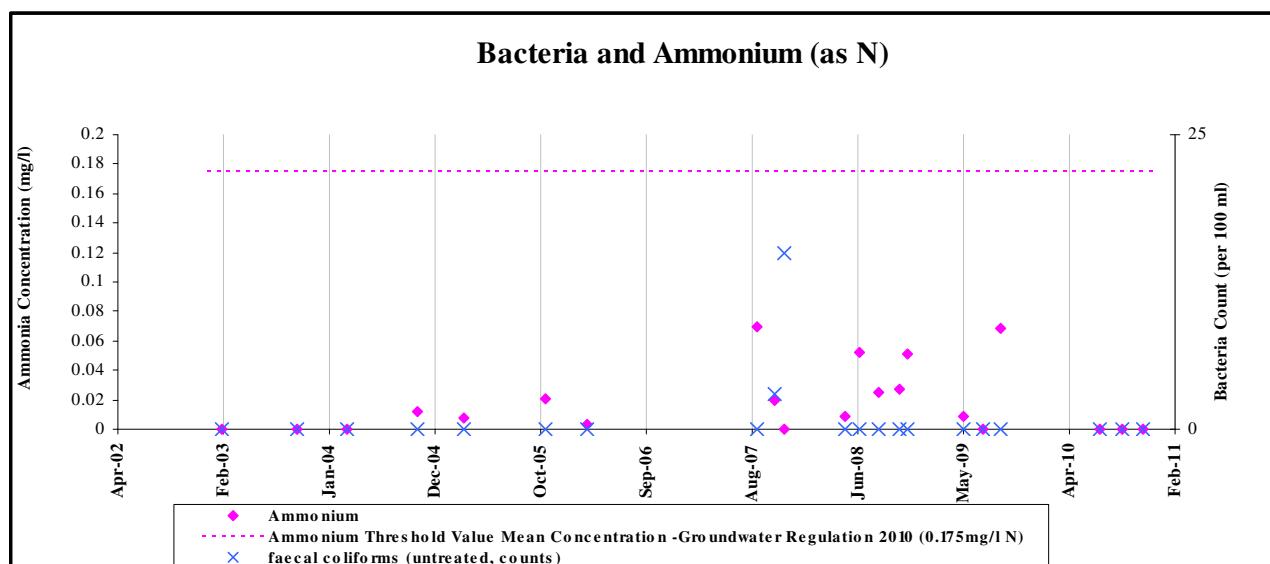

Figure 7: Key Indicators of Agricultural and Domestic Contamination: Bacteria and Ammonium

- The nitrate (as NO₃) level ranges from 12.1 mg/l to 19.9 mg/l, with a mean of 16.6 mg/l. The values are considerably below the MAC (50 mg/l) and Threshold Value of 37.5 mg/l.
- Chloride can be a constituent of organic wastes, sewage discharge and artificial fertilisers, and concentrations higher than 24 mg/l (Groundwater Threshold Value, Groundwater Regulations S.I. No. 9 of 2010) may indicate contamination, with levels higher than 30 mg/l usually indicating significant contamination (Daly, 1996). Chloride concentrations range from 24 mg/l to 47 mg/l with a mean of 29 mg/l.

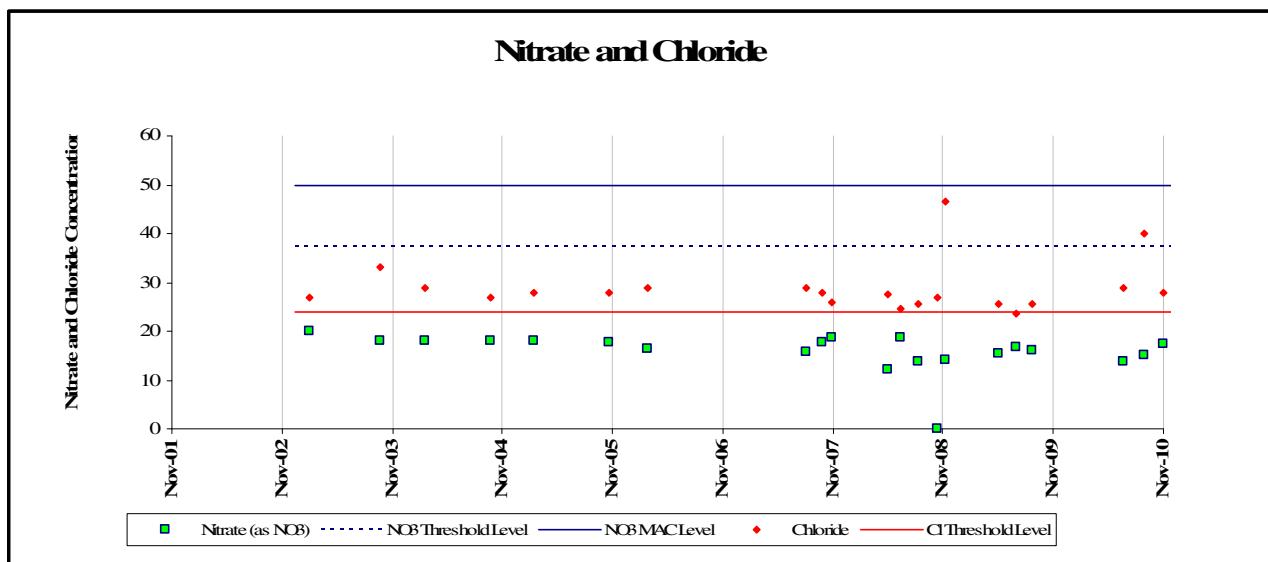

Figure 8: Key Indicators of Agricultural and Domestic Contamination: Nitrate and Chloride Graph

- The sulphate, potassium, sodium, magnesium and calcium levels are within normal ranges. The potassium: sodium ratio has never been above the threshold value of 0.35.

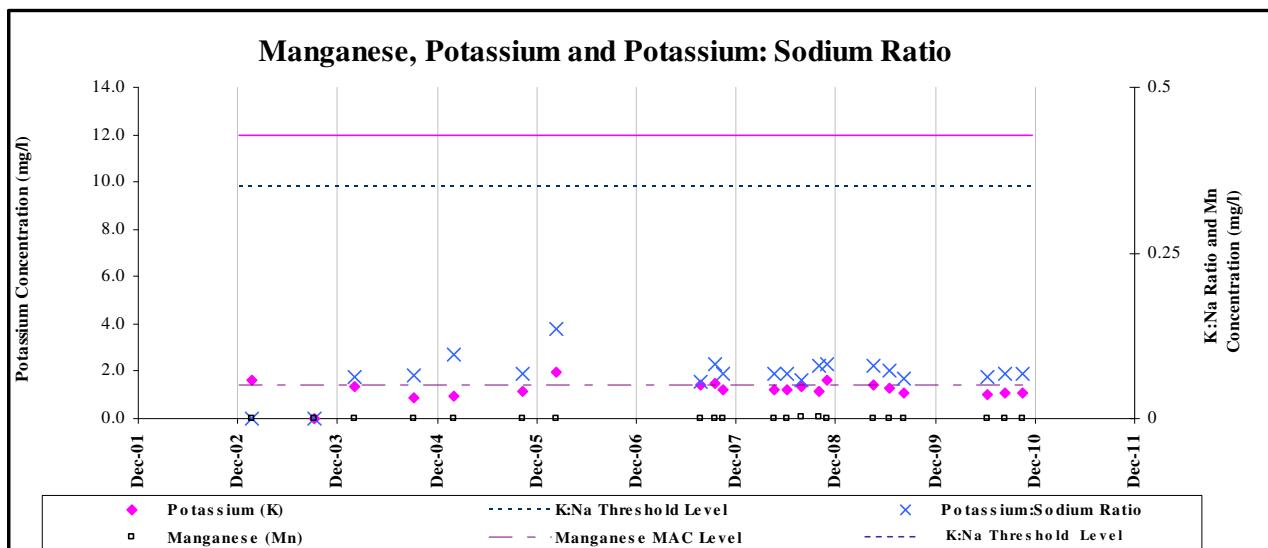

Figure 9: Key Indicators of Agricultural and Domestic Contamination: Manganese, Potassium and K/Na ratio

- Turbidity exceeded the drinking water standard limit of 1 NTU on 5 occasions. This is likely due to the presence of very fine clay particles occasionally entering the borehole.
- The concentrations of iron and manganese are within the normal ranges.
- Other trace metals were within either the normal range for good quality drinking water or were not detected.

In summary, the water is mildly acidic. There were two incidents of faecal coliform detection in 2007. While the chloride values generally exceed the Threshold Value other potential contamination indicators

(sodium: potassium) are not elevated. Trace levels of pesticides (MCPA and mecoprop) were detected once in 2007 and Trihalomethanes in 2003, 2004 and 2009. However the concentrations of pesticides and trihalomethanes were all below the groundwater regulations threshold values. The monitoring results show that while the aquifer is extremely vulnerable to contaminants the pressures are generally low.

9.4 Aquifer Characteristics

Based on the GSI geology map, the borehole abstracts water from the Campile Formation, which is classified by the GSI as a Regionally Important Fissured bedrock aquifer (Rf), as indicated in Figure 9. Groundwater flow occurs along bedding planes and through faults, fractures and fissures in the bedrock. The well provides in the range of 300–340 m³/d. The yield is sustainable and the scheme has never had problems meeting demand. During the cold weather in December 2010, the borehole was pumping at the maximum output of the pump at 410 m³/d without any observed impact on the supply.

The aquifer is classified as regionally important because of the higher groundwater yields that can be obtained from these rocks due to the presence of a high density of fractures resulting from folding and faulting during the Caledonian Orogeny mountain building phase of deformation. This formed the local Campile Syncline. The aquifer is part of the Adamstown Groundwater Body, as delineated by the GSI.

A transmissivity (T) value for Rf aquifers in this groundwater body is estimated in the Adamstown GWB Report to be 150 m²/d based on information from two supplies in the GWB.

A data logger, which measures water level and temperature, was placed in BH-1 at 10.59 am on 18/10/2011 and removed at 9.28 am on 21/10/2011. The logger measured an initial recovery period and more prolonged pumping than usual due to the manual shutting off of the borehole on the 18th October. T values were calculated for both the recovery (114 m²/d) and the prolonged pumping period (189 m²/d) using the Cooper Jacob approximation. An average value of 150 m²/d was chosen. Due to the short nature of the test the values derived here must be treated with caution as the water level did not stabilise during pumping and the water had not fully recovered.

The Logan Approximation was also used to calculate a T value of 327 m²/d. The higher Logan T value is because of the short duration of pumping and the water level was still falling. Specific capacity is a measure of the discharge of the borehole divided by the drawdown. The specific capacity and Logan T values are probably over estimated due to lack of a precise static water level and the fact that the water level was still dropping before the pump stopped. A specific capacity of 268 m³/d/m was calculated from the pumping test dataset. The results are summarised in Table 9-2 below.

A hydrogeological assessment was undertaken by K.T Cullen (KTC) in 1981 on the Bottled Water borehole which is located within 500 m to the west of the site. This involved an 11 day pumping and recovery test. The test was pumped at a constant rate of 109 m³/d. The pumping test showed a drawdown of 28.72 m after 11 days. When pumping had ceased the water level had only recovered by 17.99 m after 26 hours. Based on this data, a range of T values of 1.6 to 4.6 m²/d was calculated by the Cooper Jacob and Logan approximations. Specific capacities of 11.4 m³/d/m after 3 days and 3.86 m³/d/m at the end of the 11 day test were calculated. This is much lower than the values derived from the testing of the Camross-Adamstown WSS production boreholes. The borehole is located in different rocks, in a different section of the aquifer, and is separated from the Carrigbyrne supply by a major fault, so different hydrogeological conditions may be present locally.

KTC also completed another hydrogeological assessment on a number of boreholes for the Adamstown Water Supply Scheme in the 1980's. The wells are located between 1.7 km and 5.4 km northeast of the abstraction wells. They are also installed in the Campile formation. 9 day high yielding pumping tests were undertaken on the boreholes. The results are summarised in Table 9-2 and the locations are shown on Figure 10. The results indicate much higher T values than for the Bottled Water site ranging from 40 to 400 m²/d and are closer to those estimated for the Carrigbyrne boreholes.

The short duration of the testing on the Carrigbyrne BH-1 means the results should be treated cautiously. Especially when much lower T and specific capacity values were calculated based on a much longer test for the nearby Bottled Water borehole. The lower T values for the Bottled Water site may be influenced by its position higher in the catchment relative to the Carrigbyrne wells. It also has a much smaller zone of contribution.

Because the Logan T value is higher than the Cooper Jacob values, an average T value of 150 m²/d was derived from the values calculated by the Cooper Jacob approximation. The graphs for all the tests are included in Appendix 2.

Table 9-1; Summary of Transmissivity and Specific Capacity Values

	Discharge (m ³ /d)	Transmissivity (T m ² /d)			Specific Capacity (m ³ /d/m)
		Logan Approx.	C-J Pumping	C-J Recovery	
Carraigbyrne BH-1	528*	327	113	190	268
Bottled Water BH	109	4.6	1.6	3	3.86-11.4
TW 35/7	2033	260	406	396	233.7
TW 31/10	2100	149	100	129-409	122
TW 31/1	620	44	65	122	36

* Based on the hourly pumping rate of 22 m³/hr. Due to the reservoir capacity the maximum daily abstraction is 410 m³/d and the average daily abstraction is 300 m³/d.

The bulk hydraulic conductivity K (coefficient of permeability) can also be estimated by dividing the transmissivity by the saturated thickness of the aquifer. The saturated thickness of the aquifer locally is not known as there is no borehole log for the well. As indicated by the GSI in the Adamstown GWB Report, evidence from drilling in the Campile Formation shows that the there is an aquifer depth of 50 m for similar rocks in Kilkenny. At this site, the well is thought to be 33.1 m deep and the depth to rock is assumed to 9 m. This gives a maximum aquifer thickness of 24 m. However, based on the highest water level observed in BH-1 during recovery of 18.16 m and the static water level noted in the Bottled Water well of 18.05 m bgl in 1981, the saturated thickness is unlikely to be 24 m. Assuming a static water level of 18 m bgl the saturated thickness of the aquifer would be 15 m. As a precautionary measure a range of 15 to 24 m has been selected. Based on this assumption, the hydraulic conductivity is estimated to be 6.2 to 10 m/d. The Hydraulic Conductivity (K) estimation is summarised as follows in Table 9.2:

Table 9-2: Summary of Hydraulic Conductivity Values

	Range of values
Transmissivity (m ² /d)	150
Estimated Depth of Aquifer (m)	15.5-24
Hydraulic Conductivity (m/d)	6.2-10

The velocity of water moving through this aquifer to the borehole has been estimated using Darcy's Law:

$$v = \frac{Ki}{n}$$

where v is the groundwater velocity (m/d)

K is the hydraulic conductivity (m/d)

i is the groundwater gradient

n is the estimated effective porosity

The natural gradient is estimated at 0.08 (Section 9.2). The hydraulic conductivity is estimated to be between 6.2-10 m/d. Daly (1982) suggests storage coefficients of 1% for the unconfined state and less than 0.01% for the confined state for the Campile Formation. As the aquifer is considered unconfined a porosity of 1% was used.

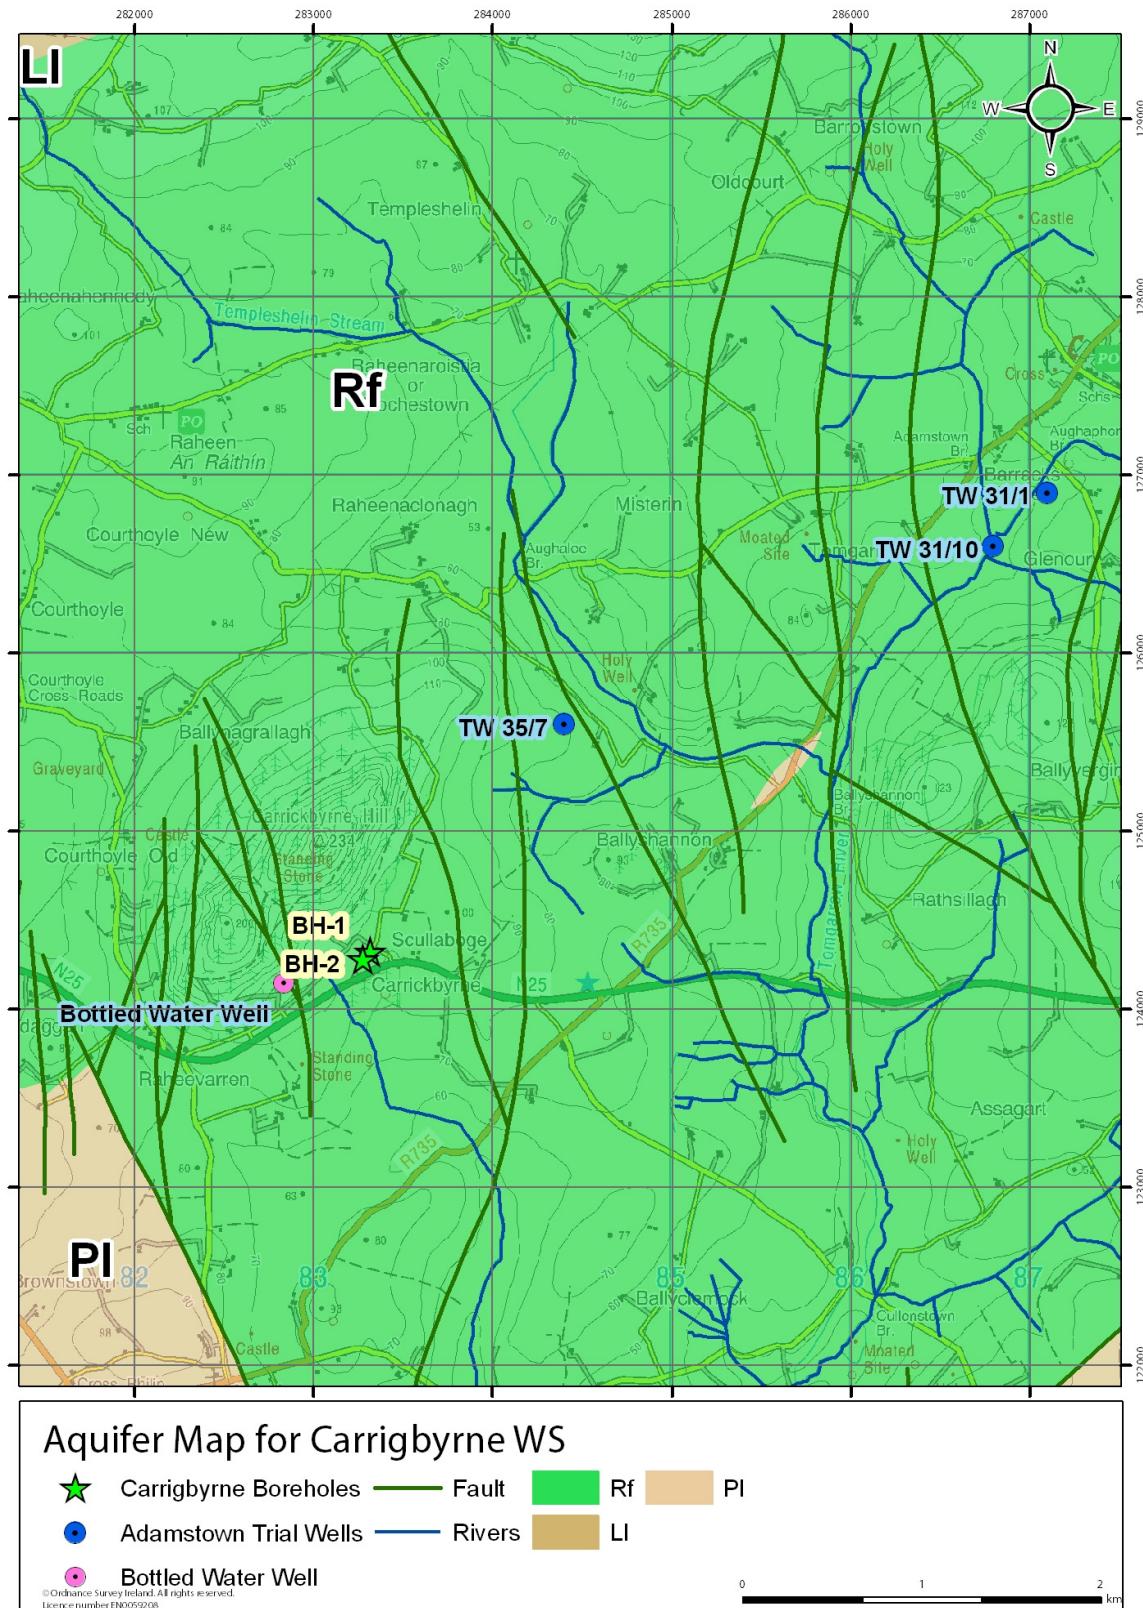

Figure 10 Aquifer Map

The aquifer parameters are summarized in Table 9-3.

Table 9-3: Indicative Parameters for the Campile Formation at Carrigbyrne

Parameters	Source of Data	BH1
Transmissivity (m^2/d)	Calculated from short pumping test	150 m^2/d
Hydraulic Conductivity(m/d)	Estimated from T value divided by aquifer thickness	6.2-10
Effective Porosity	Assumed from similar rock type in Waterford (Daly 1982)	1%
Groundwater gradient	Assumed based on topography and field observations	0.08
Velocity (m/d)	Calculated from Darcy's Law	50-80

10 Zone of contribution

The Zone of Contribution (ZOC) is the complete hydrologic catchment area to the source, or the area required to support an abstraction from long-term recharge. The size and shape of the ZOC is controlled primarily by (a) the total discharge, (b) the groundwater flow direction and gradient, (c) the subsoil and rock permeability and (d) the recharge in the area. This section describes the conceptual model of how groundwater flows to the source, including uncertainties and limitations in the boundaries, and the recharge and water balance calculations which support the hydrogeological mapping techniques used to delineate the ZOC.

10.1 Conceptual Model

The higher transmissivity and specific capacity values calculated for the Carrigbyrne wells compared to other wells in this water body is indicative of a quickly recharging, extremely vulnerable aquifer. Recharge is expected to occur up hydraulic gradient to the north of the boreholes. The majority of the recharge occurs where the felsic volcanics are exposed or close to the surface. Less recharge is expected to occur closer to the borehole because of the presence of gley soil and low permeability subsoils. The steeper gradients in the upper portions of the catchment and the combination of gley soils and shallower gradient lower in the catchment, results in significant run-off to the local streams in periods of high rainfall. The GSI Groundwater Body Report assumes groundwater in the Campile Formation has generally long deep flowpaths with the groundwater moving from north to south. Regional groundwater discharge is expected to the south where the rock type changes from the Regionally Important Fractured Campile Formation to the Poorly Productive Ballyhoge Formation which are Ordovician Metasediments (GSI 2004). The deep static groundwater levels observed in the boreholes locally in the catchment may be indicative of shallow groundwater gradients and deeper regional flow patterns in the Campile Formation. A schematic representation of the conceptual model is shown in Figure 10.

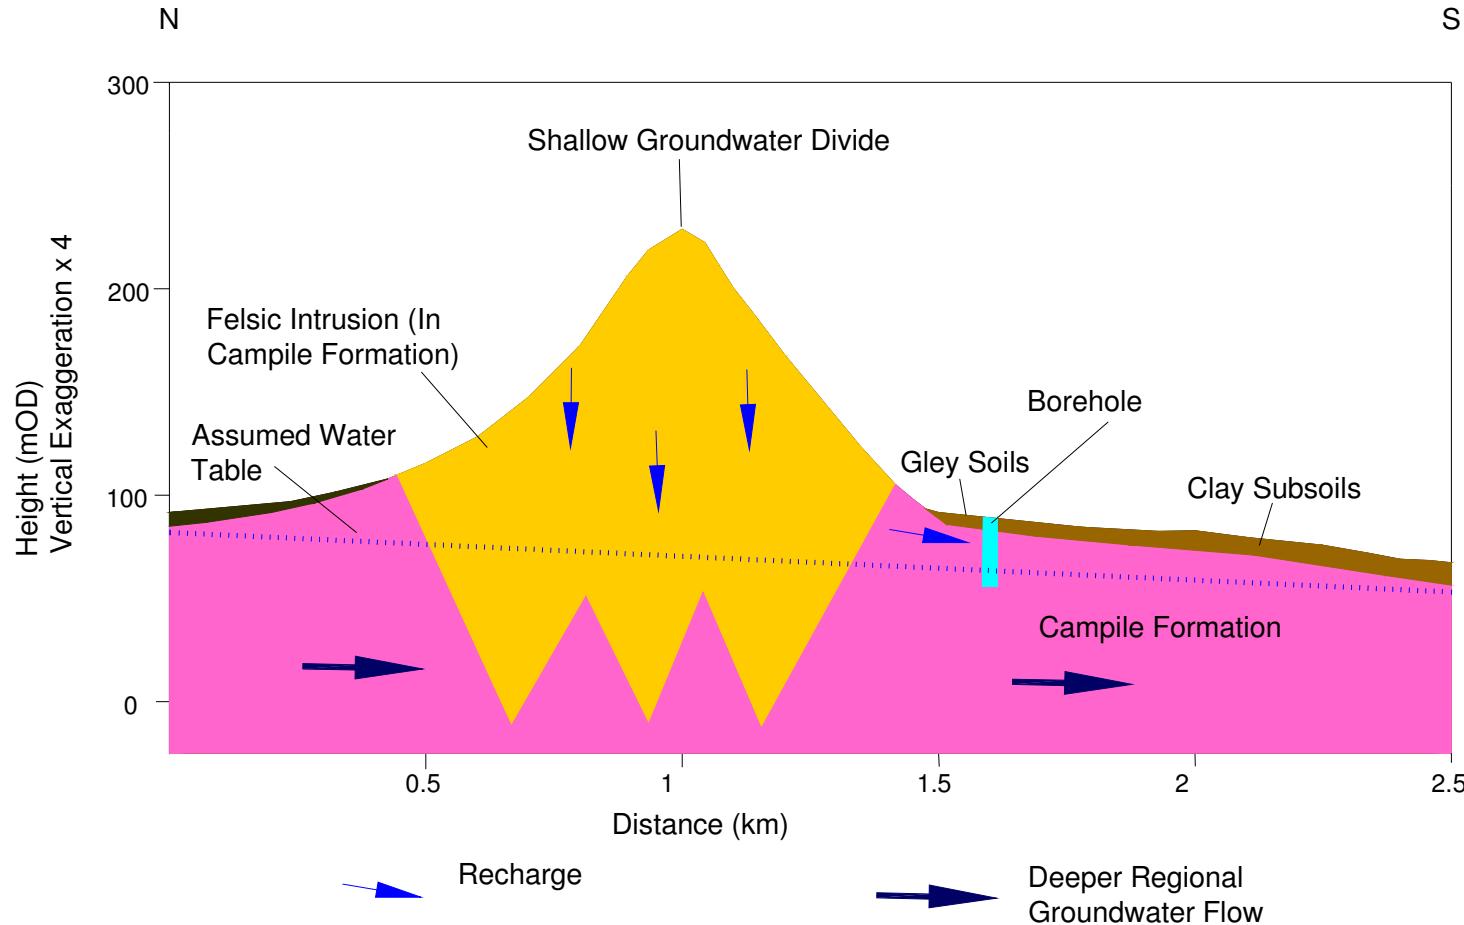

Figure 11: Conceptual Model

10.2 Boundaries of the ZOC

The boundaries of the area contributing to the source are considered to be as follows (Figure 11).

The northern, eastern and south western boundaries are primarily based on, conceptualised groundwater flow-lines, which flow to the south in the direction of the Corock River, and the size of the estimated ZOC using the recharge and water balance equations in Section 10.3. The shape of the ZOC also accounts for the possibility of fracture flow along the north-south trending fault lineaments.

The north eastern boundary is defined by the north south trending fault. Water to the west of this fault is expected to flow along the regional flow paths to the south and is not expected to reach the boreholes.

The southern boundary – the down gradient boundary is the maximum downgradient distance that the borehole can pump water from which is based on the uniform flow equation (Todd, 1980).

$$X_L = \frac{Q}{2\pi T i}$$

where Q is the daily pumping rate ($340 \text{ m}^3/\text{d}$)

T is Transmissivity (taken from aquifer characteristics $150 \text{ m}^2/\text{d}$)

i is gradient 0.08

Given the pumping rate is $340 \text{ m}^3/\text{d}$, the transmissivity is estimated as $150 \text{ m}^2/\text{d}$ and the hydraulic gradient is 0.08 the approximate maximum downgradient distance is 4.5 m. To allow for limited site specific data and associated uncertainties in the calculation of the aquifer parameters, the down gradient limit has been increased to 10 m.

10.3 Recharge and Water Balance

The term ‘recharge’ refers to the amount of water replenishing the groundwater flow system. The recharge rate is generally estimated on an annual basis, and assumed to consist of input (i.e. annual rainfall) less water loss prior to entry into the groundwater system (i.e. annual evapotranspiration and runoff). The estimation of a realistic recharge rate is critical in source protection delineation, as it will dictate the size of the zone of contribution to the source (i.e. the outer Source Protection Area).

At Carrigbyrne therefore, the main parameters involved in recharge rate estimation are: annual rainfall; annual evapotranspiration and a recharge coefficient. The recharge is estimated as follows.

Potential recharge is equivalent to 475 mm/year i.e. (Annual Effective Rainfall as outlined in Section 6).

Actual recharge: 371 mm/yr. The Campile Formation is classified as a Regionally Important fissured bedrock aquifer (Rf). The majority of the area surrounding the source (95% of the ZOC to the source) is

mapped as Extreme Vulnerability, where the bedrock outcrops. Guidance document GW5 recommends a recharge coefficient in the range of 0.60 to 1 be applied for these conditions, with an inner range of 0.80-0.90 (IWWG, 2005). A coefficient of 0.85 has been assumed for this area.

In the low lying area just upgradient of the boreholes, the material is low permeability CLAY dominated gleys. A range of 0.02 to 0.2 is suggested with an inner range of 0.1-0.2. The value of 0.15 from the inner range was applied.

Runoff losses are assumed to be 18% of the potential recharge (effective rainfall). This value is based on an assumption of c.15% runoff for 95% of the area (extreme vulnerability – rock close to surface) and 85% runoff for 5% of the area (High to Low vulnerability). The **bulk recharge** coefficient for the area is therefore estimated to be 82%.

Runoff losses: 90 mm. Runoff losses are assumed to be 18% of potential recharge.

These calculations are summarised as follows:

Average annual rainfall (R)	1000 mm
Estimated P.E.	525 mm
Estimated A.E. (95% of P.E.)	499 mm
Effective rainfall	501 mm
Potential recharge	501 mm
Runoff losses	18%
Bulk recharge coefficient	82%
Assumed Recharge	410 mm

The water balance calculation indicates that the recharge over the area contributing to the source should equal the discharge at the source. At a recharge of 410 mm/yr, an average yield of 340 m³/day would require a recharge area of 0.302 km².

To allow for daily variations in abstraction, a possible increase in demand, and for the expansion of the ZOC during dry weather periods, the GSI recommends increasing the abstraction rate by 50% for the purposes of delineating the ZOC. Only one borehole can be pumped at one time and the daily abstraction rate is limited by the size of the reservoir. Due to these constraints, a ZOC delineated using the maximum possible abstraction rate of 410 m³/day requires an area of 0.365 km². This ZOC delineated (0.478 km²) is approximately 50% larger than the upper range of the present abstraction and exceeds the area required for the maximum possible abstraction. The boundary of the ZOC is shown in Figure 11.

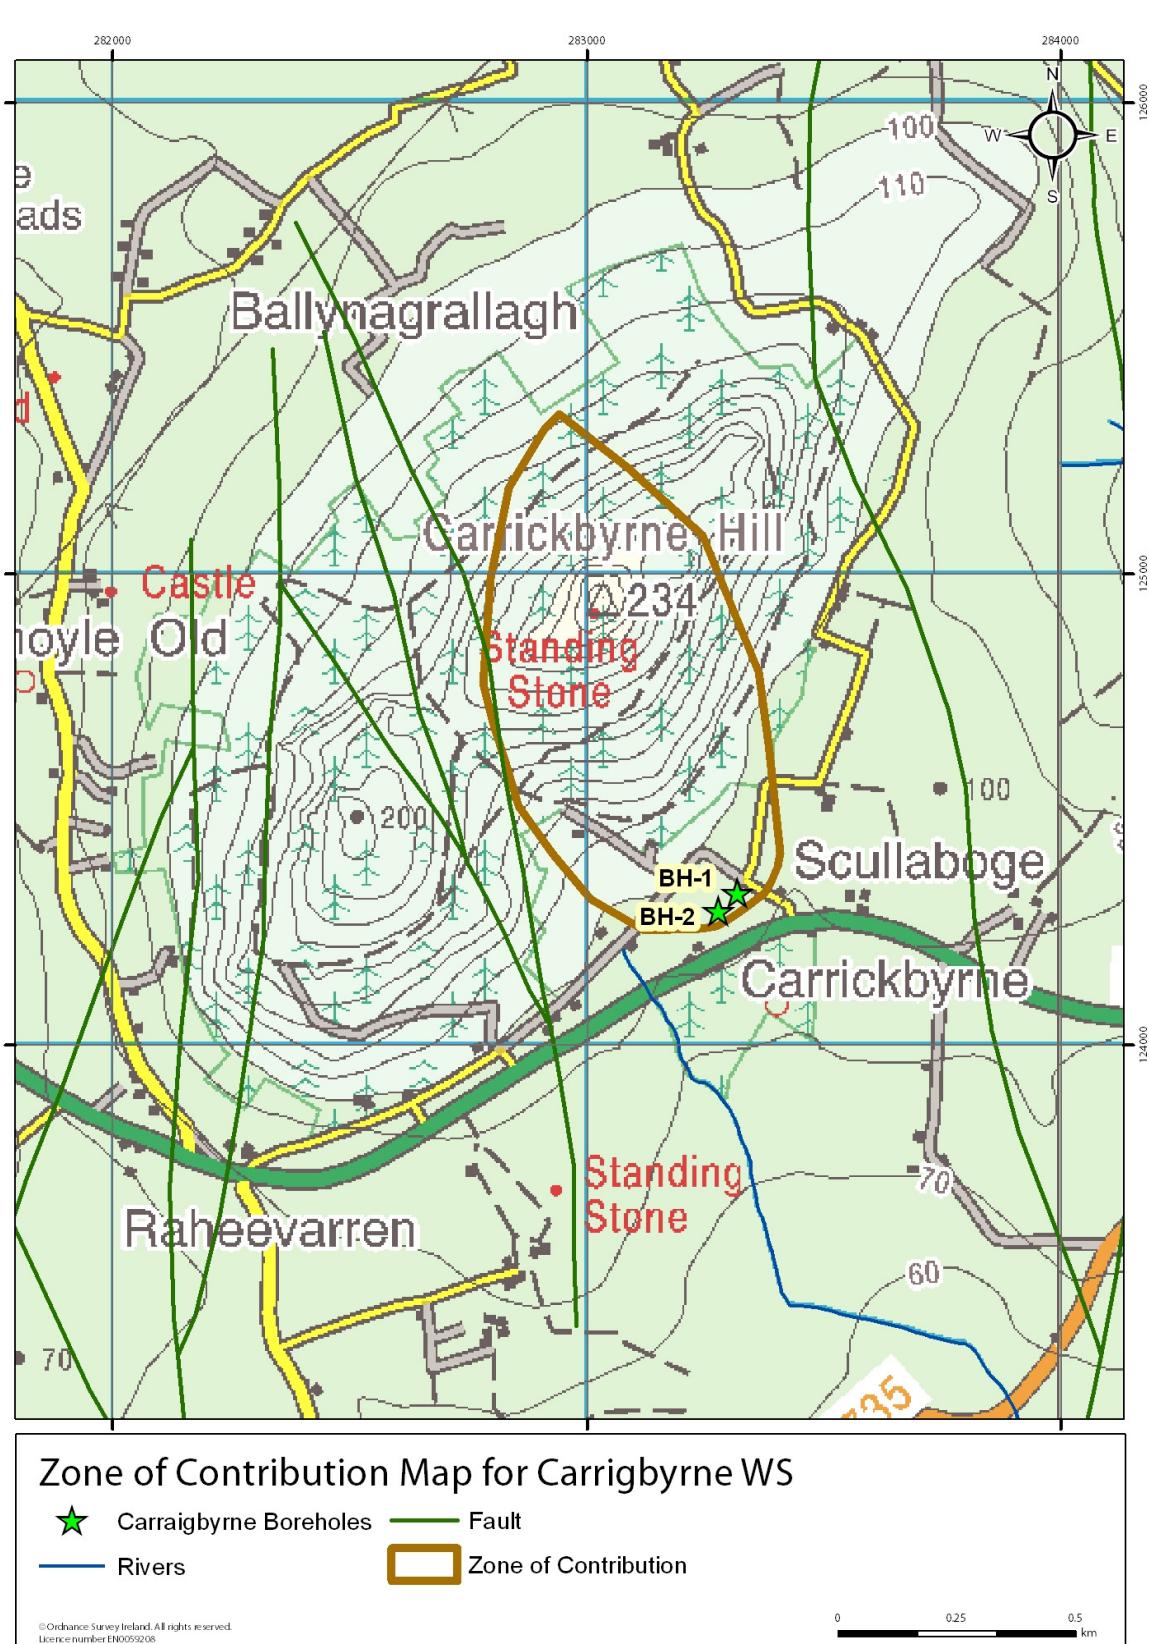

Figure 12: Zone of Contribution

11 Source Protection Zones

The SPZs are a landuse planning tool which enables an objective, geoscientific assessment of the risk to groundwater to be made. The zones are based on an amalgamation of the source protection areas and the aquifer vulnerability. The source protection areas represent the horizontal groundwater pathway to the source, while the vulnerability reflects the vertical pathway. Two source protection areas have been delineated, the Inner Protection Area and the Outer Protection Area.

The Inner Protection Area (SI) is designed to protect the source from microbial and viral contamination and it is based on the 100-day time of travel to the supply (DELG/EPA/GSI 1999). Based on the indicative aquifer parameters presented in Section 9.4, the groundwater velocity is 50-80 m/d. Hence, the minimum 100-day time range of travel would be 5 km. This is much larger than the size of the ZOC. The value is high based on the calculated transmissivity and shallow assumed hydraulic gradient in the catchment. The entire ZOC is deemed to be the Inner Source Protection Area (SI) and there is no Outer Source Protection Area (SO)

The groundwater Source Protection Zones are shown in Figure 13 and are listed in Table 11-1. The whole ZOC is included in the SI and they include SI/X, SI/E, SI/H, SI/M and SI/L. The majority of the ZOC is designated as SO/X.

Table 11-1 Source Protection Zones

Source Protection Zone		% of total area (km²)
SI/X	Inner Source Protection area / ≤1 m subsoil	76.9% (0.368 km ²)
SI/E	Inner Source Protection area / <3 m subsoil	16.2% (0.077 km ²)
SI/H	Inner Source Protection area / High vulnerability	2.7% (0.013 km ²)
SI/M	Inner Source Protection area / Moderate vulnerability	1.1% (0.005 km ²)
SI/L	Inner Source Protection area / Low vulnerability	3.1% (0.015 km ²)

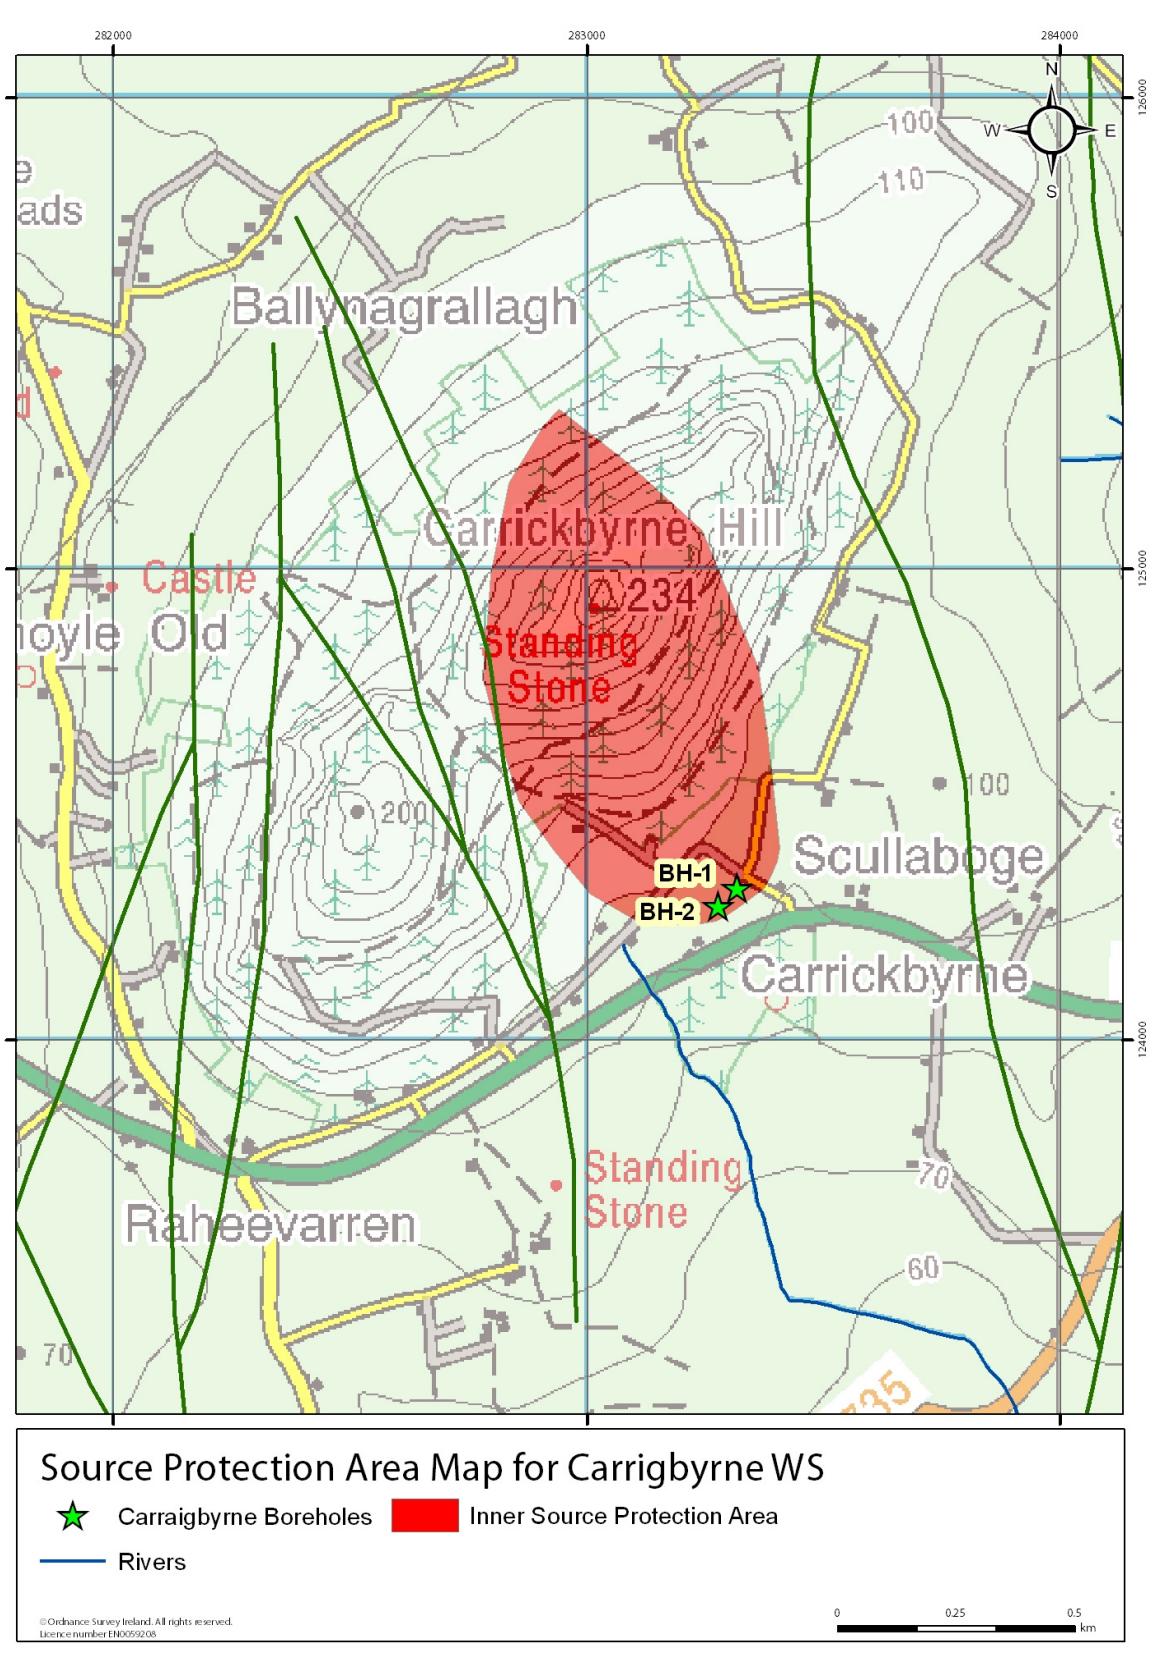

Figure 13: Inner Source Protection Area

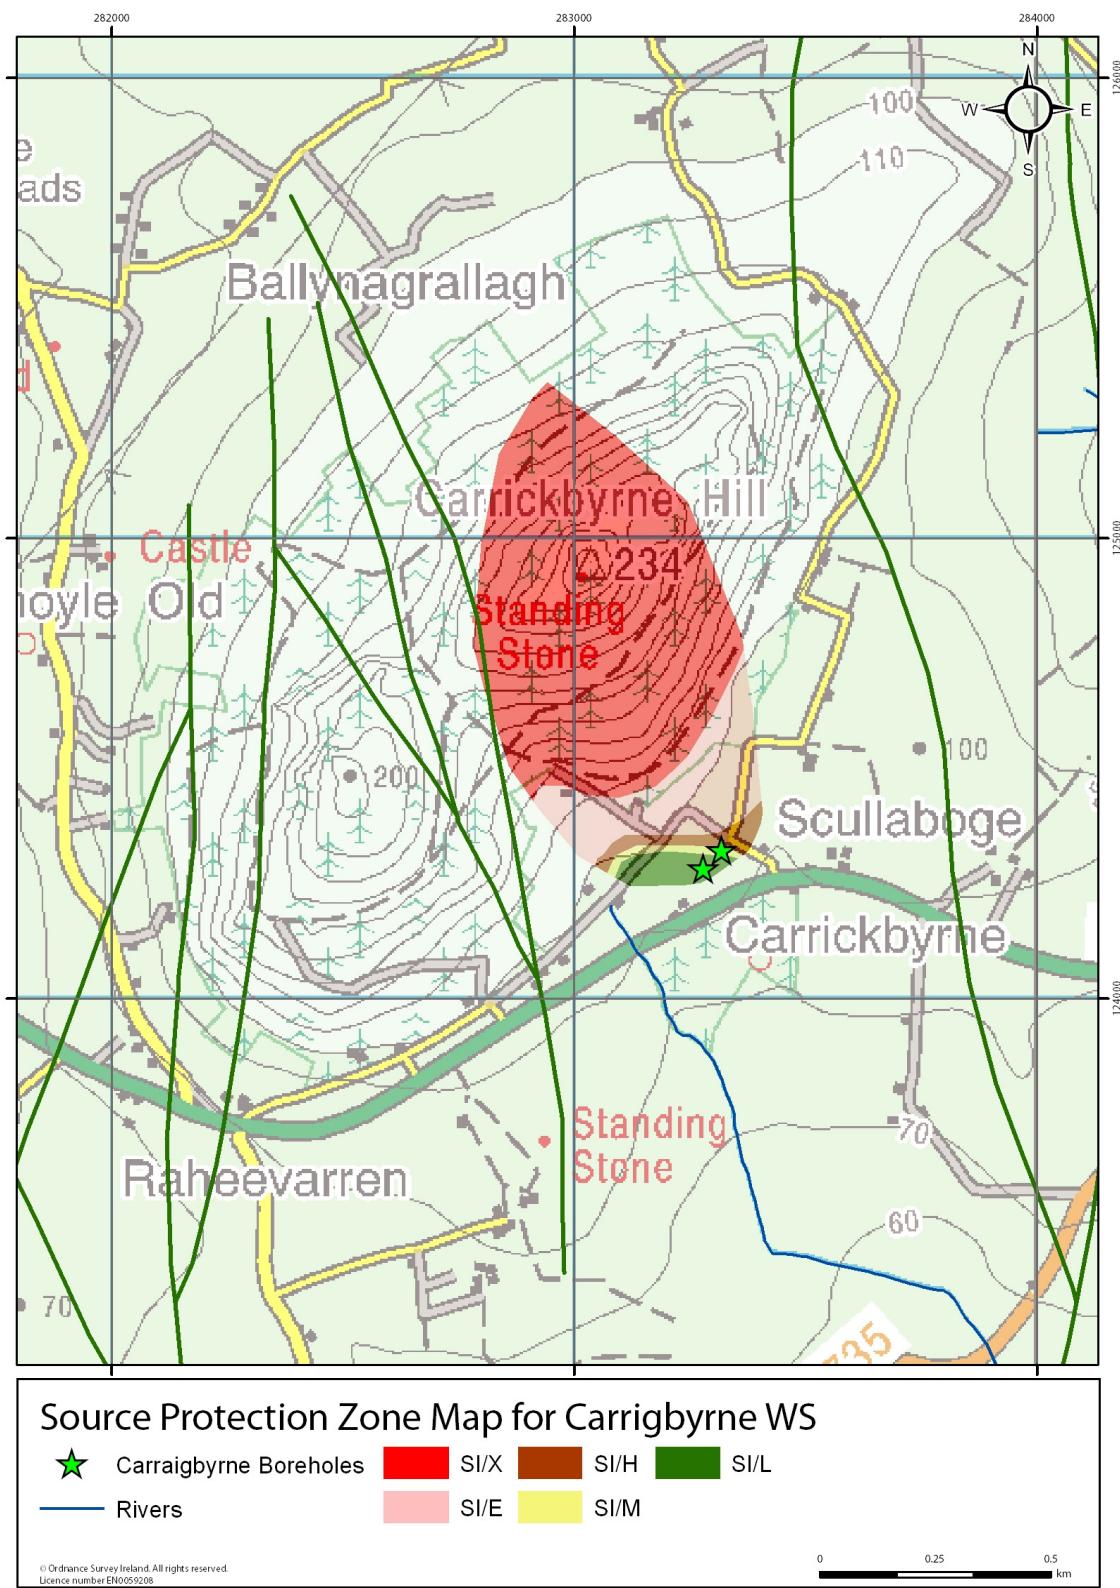

Figure 14: Source Protection Zones

12 Potential Pollution Sources

The borehole is located in a securely fenced and locked compound and the well heads are enclosed in concrete chambers to protect against the inflow of contaminated surface or shallow subsurface water. The ground surface in the compound comprises hardcore gravels.

Due to the high velocity, the entire ZOC is considered an Inner Source Protection Area as groundwater could reach the source from anywhere in the ZOC within 100 days. The main potential microbial pollution sources are individual on-site wastewater treatment systems of the dwellings. There are seven dwellings and a Pet Farm located within the ZOC. Faecal coliforms have been detected twice in 2007 in the well water indicating that these potential pollution sources could probably have an impact on the water supply. There have been no detections since the upgrading of the borehole headworks and construction of the concrete chambers. There is some land for grazing and the Pet Farm located within the ZOC. However these activities are located over poorly permeable soils and subsoils where the vulnerability is low. The rest of the land use up hydraulic gradient of the source is mixed forestry. Combined with the improved well head protection the potential risk from cryptosporidium and viruses is low.

There is a vehicle repair and sales garage located 300 m up hydraulic gradient of the wells where the bedrock is close to or at the surface. While the site appears to be well maintained this is a potential point source of hydrocarbon and or VOC contamination of the water supply well.

13 Conclusions

The Carrigbyrne Water Supply Scheme comprises two boreholes installed in 1960s. Only one borehole is pumped at a time. The borehole abstracts water from the Campile Formation. The aquifer is classified as a Regionally Important fractured bedrock aquifer (Rf). The well provides 300–340 m³/d and is pumped to a reservoir after treatment. The water is chlorinated and corrected for low pH. The well in use generally pumps between three to five hours per cycle depending on demand. This pumping rate has been sustainable since the wells were commissioned in the 1960s. Water quality is generally good but is slightly acidic. They have been occasional detections of faecal coliforms, herbicides and trihalomethanes. The pressures are moderate to low in the catchment with the land use being mainly grazing in the low ground and forestry in the steeper, upper part of the catchment.

The groundwater vulnerability within the ZOC is Extreme and Extreme with Rock close in the steep, high ground to the north. There is a sharp break in slope up gradient of the borehole where the vulnerability changes from high to low. The vulnerability at the boreholes is low and it is the dominant type in the low lying part of the catchment. The delineated ZOC is 0.413 km².

The source protection zones are based on the current understanding of the groundwater conditions and the available data. Additional data obtained in the future may require amendments to the protection zone boundaries.

14 Recommendations

The following actions are recommended:

- That the water quality monitoring programme should include for pesticides on an annual basis.
- Access to the wells to dip water levels is limited. The installation of dip tubes to allow for monitoring of water levels in both boreholes is recommended.
- The pumping cycle should be reviewed to establish if the duration of pumping could be increased to prolong the operational lifespan of the pumps. An assessment of the water levels set in the pumping reservoir to activate the pumping sequence may be required to determine if a longer pumping duration is feasible.

APPENDIX 1

**Geological Survey of Ireland: Adamstown Groundwater Body
Description (1st Draft) (2004).**

Adamstown GWB: Summary of Initial Characterisation.

Hydrometric Area Local Authority	Associated surface water bodies	Associated terrestrial ecosystems	Area (km ²)
13 –Coastal area Wexford Co Co	Corock, Owenduff, Tintern Abbey Stream and Barrow estuary.	Boley Fen, Barrow River Estuary	181
Topography	The drainage pattern in this aquifer reflects the reduction in elevation from north to south. The highest point within the groundwater body area is Carrickbyrne Hill at 234m OD. The lowest areas in the groundwater body are to the west at the mouth of the River Barrow around Campile, which is at sea level.		
Geology and Aquifers	Aquifer type(s)	<p><u>Mostly:</u> Rf: Regionally Important Fractured aquifer. <u>With Smaller areas of:</u> Ll: Locally important aquifer which is moderately productive only in local zones Pl: Poor aquifer which is generally unproductive except for local zones</p> <p><u>Mostly:</u> Ordovician Volcanics <u>With Smaller areas of:</u> Devonian Old Red Sandstones Granites & other Igneous Intrusive rocks Ordovician Metasediments This rock contains areas of felsic volcanic rock which are believed to be the main water bearing components.</p>	
	Key structures.	The bedrock is highly fractured and broken due to folding and faulting in the Caledonian Orogeny, which formed the Campile Syncline. Superimposed upon this are a series of minor folds giving rise to pronounced cleavage. The crystalline volcanic rocks will have ruptured under the mountain building forces that affected the whole area. The rock units are steeply dipping to the south.	
	Key properties	Wells tested at Adamstown and Carrickbyrne Hill have yields of 1400m ³ /d, specific capacities of 44.7m ³ /d/m and transmissivity values in the region of 150m ² /d	
	Thickness	The effective thickness of this aquifer could be quite large. Well logging data from Kilkenny shows large fractures open at depths of 50m.	
	Lithologies	<p>The Clogga Till is a stone clay sand based till containing large angular cobbles and boulders chiefly of shale and granite.</p> <p>There are also some significant silty alluvium deposits close to the Barrow River estuary. In places there appear to be sand and gravel layers of about 6.5m between the bedrock and the overlying silt.</p>	
Overlying Strata	Thickness	Thickness has been shown to be mostly less than 10m but may increase closer to the Barrow, as alluvial deposits become thicker.	
	% area aquifer near surface	[Information will be added at a later date]	
	Vulnerability	[Information will be added at a later date]	
	Main recharge mechanisms	Rainfall recharges largely in the north where overlying strata may be thinner in the uplands. Also in locations like Carrickbyrne Hill which appear to coincide with areas where felsic volcanics outcrop.	
Recharge	Est. recharge rates	[Information will be added at a later date]	
	Spring and large known abstractions (m ³ /d)	Adamstown (1400), Carrigbyrne (204).	
	Main discharge mechanisms	The most likely areas for this groundwater body to discharge will be to the associated surface water bodies. This may occur mostly at the geological contact between this groundwater body and the body to the south. It is possible that water could be forced to the surface and into surface water bodies here.	
Discharge	Hydrochemical Signature	Low mineralized nature is noteworthy. Waters monitored are shown to be moderately soft to slightly hard. Average electrical conductivity values are Carrigbyrne 418, Tellerought 283 and Ballinamona 384 (µs/cm), low values which confirm low mineralised water. There is evidence of saltwater intrusion at Great Island, Wexford. The bedrock strata of this groundwater body are Siliceous .	
	Groundwater Flow Paths	Groundwater flow may be in long flowpaths from north to south. There may be a small/local groundwater divide where some flow will be to the west towards Campile and the Barrow River estuary and the rest will flow south. In areas like Carrickbyrne there will probably be elevated groundwater levels which would radiate from the peak but probably taper towards the south with the regional flow system. Groundwater flow has been estimated at 8m/yr in the extreme west area of the body at Great Island Power Station.	
Groundwater and surface water interactions	There is likely to be an important groundwater connection to Boley Fen, which lies on a geological contact between two groundwater bodies of differing aquifer classification. The relevance of this requires further investigation.		

Conceptual model	This groundwater body is defined to the northwest and southeast by the extent of the Campile Formation. The Barrow River defines the western boundary and the boundary of Hydrometric area 13 defines the northern boundary. Groundwater is mostly recharged in the north and at various hills in the area. Regional flow is mostly north to south. There is probably a local groundwater divide in the area east of Campile. West of this divide, groundwater discharges to the Barrow Estuary and northeast of this, probably discharges to the associated surface water bodies, especially at the geological contact at the southern boundary of the body.

REPORT ON THE DRILLING AND TEST PUMPING

**OF A
TRIAL WELL AT CARRICKBYRNE, CO. WEXFORD. 22nd September, 1981**

I. INTRODUCTION.

This Report, dated 22nd September, 1981, describes the drilling and test pumping of a trial water well at Carrickbyrne, Co. Wexford, during the Summer of 1981. The Report lists the analyses of water samples from the trial well and compares them to (a) the chemistry of water from the nearby Local Authority production well and (b) the E.E.C. Standards for potable water.

The works and studies outlined in this Report were commissioned by Mr. P. Dubsky to determine if a well at Carrickbyrne could be developed as a source of mineral water.

II. LOCATION OF TRIAL WELL.

The trial well was located on land owned by Mr. P. Dubsky on the southern slopes of Carrickbyrne Hill. The well site is bounded immediately by evergreen forest to the north and west, and by agricultural land to the east and south.

Mr. Dubsky's property lies some 106~114m above ordnance datum and some 0.4 Km from the production well supplying the Carrickbyrne Group Scheme.

III. DRILLING.

O'Donohoe Brothers of Gorey, drilling contractors, were retained to drill the trial well. Drilling commenced on August 10th, 1981 and continued until August 13th. The drilling contractor used a rotary drilling rig with compressed air as the flushing medium.

A 200 m.m. hole was drilled to a depth of 9m through the overburden and for 4m into the underlying rock. Three lengths (9m) of 150 m.m. (I.D.) thermoplastic casing was installed in the 200 m.m. hole. Drilling was then continued and the hole deepened to the finished depth of 61m at a diameter of 150 m.m.

The overburden was 5m thick and consisted of loose gravel and weathered rock overlying bedrock of light coloured rhyolite. The rhyolite gave way to a dark coloured igneous rock (probably andesitic in composition) at a depth of 28m which continued to the bottom of the hole at 61m.

Significant inflows of water were recorded at 20, 27 and 50m below ground level. On completion of the drilling the well was developed with compressed air for 2 hours, the water becoming clear within a few minutes of development starting.

IV. TEST PUMPING.

Mr. S. Kelly of Courtmacuddy was retained to test pump the well. The testing began on August 20th, 1981 and continued without interruption for a period of 264.5 hours with recovery starting on September 1st. The well was pumped with a submersible pump powered by a diesel driven generator. The pumped water was carried off Mr. Dubsky's property and flowed into a surface water drain, a distance of 200m from the well head. The trial well was pumped at a constant rate of $109\text{m}^3/\text{day}$. Water levels were measured at regular intervals in the trial both during the pumping and recovery phases. Appendix I of this Report contains the water levels measured during the test pumping exercise.

An analysis of the time-drawdown data shows that the rate of fall of the water level is affected by the level of water in the well. This feature is characteristic of groundwater flow in fissured rocks and reflects the draining of various fissures as the water levels falls with pumping. The test pumping exercise has shown that the trial well is capable of a sustained yield of $109\text{m}^3/\text{day}$ with a drawdown of 28.5m. However, due to the variation of the rate of water level decline the specific capacity of the well can be given as $11.4\text{m}^3/\text{day}/\text{m}$ after 3 days of pumping or as $3.86\text{m}^3/\text{day}/\text{m}$ after 11 days of continuous pumping. This variation of specific capacity

with pumping duration means that a greater volume of water can be obtained from the well per meter of drawdown when the water level remains above 30m than when the pumping level falls below 30m.

Using the above figures a production demand of $300\text{m}^3/\text{day}$ (66,000 g.p.d.) for an 8-hour day would see a drawdown of 8.8m and a pumping level of 27.5m. The intervening 16-hours would allow the well to recover.

V. CHEMICAL ANALYSES.

Samples of the water pumped from the trial well were collected at the well head and delivered to the I.I.R.S. for chemical and bacteriological analysis. Two samples were collected after 72 hours of pumping, one for chemical and one for bacteriological analysis. One sample was taken from the trial well at the end of the pump test and together with a sample from the nearby Local Authority pumping well, were sent for chemical analysis. The results of these analyses and the results of a previous analysis of the water from the Group Scheme well are brought together in Table I below and compared with the E.E.C. standards for potable water.

It is clear from Table I that the chemistry of the water pumped from the trial well changed slightly during the duration of the test pumping as is evident from the variation in sulphate, nitrate, calcium and bicarbonate values.

The chemistry of the Group Scheme well water is similar to that of the trial well with small differences in the calcium, magnesium and sulphate concentrations. The variation of the well water chemistry with time is also seen in the Group Scheme well with nitrate levels changing from a high of 9.7 mg/l to 3.2 mg/l between the Summers of 1980 and 1981. Whether this variation in nitrate levels is seasonal or affected by outside influences can only be determined by regular monitoring of the groundwater chemistry.

The relatively high levels of sodium and chloride in these groundwaters (Highland Spring, Na= 12.5, Cl = 15.6) is attributed to the proximity of Carrickbyrne to the sea with the result that precipitation in this region carries an unusually high concentration of these salts. The average chlorine level in Irish groundwater is 28 mg/l but this overall average is from

means for each aquifer ranging from 14.7 mg/l in the Castlecomer sandstone to 40 mg/l in the limestone dolomite aquifer of south Wexford.

Table I shows the waters tested from the Carrickbyrne area conform to the chemical standards of the E.E.C. directive on potable water quality. However, although the bacteriological analyses show no coliform bacteria present in the samples tested the colony count carried out on the sample of August 24th, gave a result that falls outside the E.E.C. standards.

Colony counts are not essential for assessing the safety of domestic water supplies. They are useful for indicating the efficiency of certain processes in water treatment and the cleanliness of the distribution system. They are also useful for determining the suitability of a water supply for the large-scale preparation of food and drink where, in order to avoid the risk of spoilage, the water should ideally contain few organisms of any kind. The high cell count recorded from the Carrickbyrne well may have been caused by soil or dust gaining access to the well during development.

VI. CONCLUSIONS AND RECOMMENDATIONS.

The results of the present drilling and testing programme show that the trial well at Carrickbyrne Hill is capable of a sustained yield of 109m³/day for 11 days and that the pumped water is of an exceptionally low mineralised character.

The water pumped from the trial well satisfies all but one of the E.E.C. standards for potable water but this divergence in the colony count may be related to the well development and so not a permanent feature. Changes in groundwater chemistry with time and pumping were noted in both the trial and Group Scheme wells especially in the sulphate and nitrate levels.

It is recommended that pumped samples be collected and analysed from both the trial and Group Scheme wells during late January and February of 1982 when groundwater levels are the highest, and the aquifer replenished by Winter recharge. These samples will show whether the low nitrate levels recorded in the last pair of analyses are annual low values and

whether the marginally high colony count is a permanent feature
of the Carrickbyrne trial well.

APPENDIX I.

Time-Drawdown Data from Test Pumping of Trial Well.

此後，我便在這裏住了一年多。這一年，我對中國的社會、政治、經濟、文化等各個方面都有了較深的了解。我還寫了不少文章，發表在《新民報》、《大公報》、《中華報》等報紙上。我還和一些知識分子、社會活動家、政治家進行了廣泛的接觸，交到了許多朋友。我還參加了許多社會團體，如中國民主黨派聯合委員會、中國民主同盟、中國民主建國黨等。我還參與了中國民主黨派聯合委員會的籌建工作，並擔任了中國民主黨派聯合委員會的秘書長。我還參與了中國民主黨派聯合委員會的籌建工作，並擔任了中國民主黨派聯合委員會的秘書長。我還參與了中國民主黨派聯合委員會的籌建工作，並擔任了中國民主黨派聯合委員會的秘書長。

Adamstown GWB: Summary of Initial Characterisation.

Hydrometric Area Local Authority	Associated surface water bodies	Associated terrestrial ecosystems	Area (km ²)
13 –Coastal area Wexford Co Co	Corock, Owenduff, Tintern Abbey Stream and Barrow estuary.	Boley Fen, Barrow River Estuary	181
Topography	The drainage pattern in this aquifer reflects the reduction in elevation from north to south. The highest point within the groundwater body area is Carrickbyrne Hill at 234m OD. The lowest areas in the groundwater body are to the west at the mouth of the River Barrow around Campile, which is at sea level.		
Geology and Aquifers	Aquifer type(s)	<p><u>Mostly:</u> Rf: Regionally Important Fractured aquifer. <u>With Smaller areas of:</u> Ll: Locally important aquifer which is moderately productive only in local zones Pl: Poor aquifer which is generally unproductive except for local zones</p> <p><u>Mostly:</u> Ordovician Volcanics <u>With Smaller areas of:</u> Devonian Old Red Sandstones Granites & other Igneous Intrusive rocks Ordovician Metasediments This rock contains areas of felsic volcanic rock which are believed to be the main water bearing components.</p>	
	Key structures.	The bedrock is highly fractured and broken due to folding and faulting in the Caledonian Orogeny, which formed the Campile Syncline. Superimposed upon this are a series of minor folds giving rise to pronounced cleavage. The crystalline volcanic rocks will have ruptured under the mountain building forces that affected the whole area. The rock units are steeply dipping to the south.	
	Key properties	Wells tested at Adamstown and Carrickbyrne Hill have yields of 1400m ³ /d, specific capacities of 44.7m ³ /d/m and transmissivity values in the region of 150m ² /d	
	Thickness	The effective thickness of this aquifer could be quite large. Well logging data from Kilkenny shows large fractures open at depths of 50m.	
	Lithologies	<p>The Clogga Till is a stone clay sand based till containing large angular cobbles and boulders chiefly of shale and granite.</p> <p>There are also some significant silty alluvium deposits close to the Barrow River estuary. In places there appear to be sand and gravel layers of about 6.5m between the bedrock and the overlying silt.</p>	
Overlying Strata	Thickness	Thickness has been shown to be mostly less than 10m but may increase closer to the Barrow, as alluvial deposits become thicker.	
	% area aquifer near surface	[Information will be added at a later date]	
	Vulnerability	[Information will be added at a later date]	
	Main recharge mechanisms	Rainfall recharges largely in the north where overlying strata may be thinner in the uplands. Also in locations like Carrickbyrne Hill which appear to coincide with areas where felsic volcanics outcrop.	
Recharge	Est. recharge rates	[Information will be added at a later date]	
	Spring and large known abstractions (m ³ /d)	Adamstown (1400), Carrigbyrne (204).	
	Main discharge mechanisms	The most likely areas for this groundwater body to discharge will be to the associated surface water bodies. This may occur mostly at the geological contact between this groundwater body and the body to the south. It is possible that water could be forced to the surface and into surface water bodies here.	
Discharge	Hydrochemical Signature	Low mineralized nature is noteworthy. Waters monitored are shown to be moderately soft to slightly hard. Average electrical conductivity values are Carrigbyrne 418, Tellerought 283 and Ballinamona 384 (µs/cm), low values which confirm low mineralised water. There is evidence of saltwater intrusion at Great Island, Wexford. The bedrock strata of this groundwater body are Siliceous .	
	Groundwater Flow Paths	Groundwater flow may be in long flowpaths from north to south. There may be a small/local groundwater divide where some flow will be to the west towards Campile and the Barrow River estuary and the rest will flow south. In areas like Carrickbyrne there will probably be elevated groundwater levels which would radiate from the peak but probably taper towards the south with the regional flow system. Groundwater flow has been estimated at 8m/yr in the extreme west area of the body at Great Island Power Station.	
Groundwater and surface water interactions	There is likely to be an important groundwater connection to Boley Fen, which lies on a geological contact between two groundwater bodies of differing aquifer classification. The relevance of this requires further investigation.		

Conceptual model	This groundwater body is defined to the northwest and southeast by the extent of the Campile Formation. The Barrow River defines the western boundary and the boundary of Hydrometric area 13 defines the northern boundary. Groundwater is mostly recharged in the north and at various hills in the area. Regional flow is mostly north to south. There is probably a local groundwater divide in the area east of Campile. West of this divide, groundwater discharges to the Barrow Estuary and northeast of this, probably discharges to the associated surface water bodies, especially at the geological contact at the southern boundary of the body.

REPORT ON THE DRILLING AND TEST PUMPING

**OF A
TRIAL WELL AT CARRICKBYRNE, CO. WEXFORD. 22nd September, 1981**

I. INTRODUCTION.

This Report, dated 22nd September, 1981, describes the drilling and test pumping of a trial water well at Carrickbyrne, Co. Wexford, during the Summer of 1981. The Report lists the analyses of water samples from the trial well and compares them to (a) the chemistry of water from the nearby Local Authority production well and (b) the E.E.C. Standards for potable water.

The works and studies outlined in this Report were commissioned by Mr. P. Dubsky to determine if a well at Carrickbyrne could be developed as a source of mineral water.

II. LOCATION OF TRIAL WELL.

The trial well was located on land owned by Mr. P. Dubsky on the southern slopes of Carrickbyrne Hill. The well site is bounded immediately by evergreen forest to the north and west, and by agricultural land to the east and south.

Mr. Dubsky's property lies some 106~114m above ordnance datum and some 0.4 Km from the production well supplying the Carrickbyrne Group Scheme.

III. DRILLING.

O'Donohoe Brothers of Gorey, drilling contractors, were retained to drill the trial well. Drilling commenced on August 10th, 1981 and continued until August 13th. The drilling contractor used a rotary drilling rig with compressed air as the flushing medium.

A 200 m.m. hole was drilled to a depth of 9m through the overburden and for 4m into the underlying rock. Three lengths (9m) of 150 m.m. (I.D.) thermoplastic casing was installed in the 200 m.m. hole. Drilling was then continued and the hole deepened to the finished depth of 61m at a diameter of 150 m.m.

The overburden was 5m thick and consisted of loose gravel and weathered rock overlying bedrock of light coloured rhyolite. The rhyolite gave way to a dark coloured igneous rock (probably andesitic in composition) at a depth of 28m which continued to the bottom of the hole at 61m.

Significant inflows of water were recorded at 20, 27 and 50m below ground level. On completion of the drilling the well was developed with compressed air for 2 hours, the water becoming clear within a few minutes of development starting.

IV. TEST PUMPING.

Mr. S. Kelly of Courtmacuddy was retained to test pump the well. The testing began on August 20th, 1981 and continued without interruption for a period of 264.5 hours with recovery starting on September 1st. The well was pumped with a submersible pump powered by a diesel driven generator. The pumped water was carried off Mr. Dubsky's property and flowed into a surface water drain, a distance of 200m from the well head. The trial well was pumped at a constant rate of $109\text{m}^3/\text{day}$. Water levels were measured at regular intervals in the trial both during the pumping and recovery phases. Appendix I of this Report contains the water levels measured during the test pumping exercise.

An analysis of the time-drawdown data shows that the rate of fall of the water level is affected by the level of water in the well. This feature is characteristic of groundwater flow in fissured rocks and reflects the draining of various fissures as the water levels falls with pumping. The test pumping exercise has shown that the trial well is capable of a sustained yield of $109\text{m}^3/\text{day}$ with a drawdown of 28.5m. However, due to the variation of the rate of water level decline the specific capacity of the well can be given as $11.4\text{m}^3/\text{day}/\text{m}$ after 3 days of pumping or as $3.86\text{m}^3/\text{day}/\text{m}$ after 11 days of continuous pumping. This variation of specific capacity

with pumping duration means that a greater volume of water can be obtained from the well per meter of drawdown when the water level remains above 30m than when the pumping level falls below 30m.

Using the above figures a production demand of $300\text{m}^3/\text{day}$ (66,000 g.p.d.) for an 8-hour day would see a drawdown of 8.8m and a pumping level of 27.5m. The intervening 16-hours would allow the well to recover.

V. CHEMICAL ANALYSES.

Samples of the water pumped from the trial well were collected at the well head and delivered to the I.I.R.S. for chemical and bacteriological analysis. Two samples were collected after 72 hours of pumping, one for chemical and one for bacteriological analysis. One sample was taken from the trial well at the end of the pump test and together with a sample from the nearby Local Authority pumping well, were sent for chemical analysis. The results of these analyses and the results of a previous analysis of the water from the Group Scheme well are brought together in Table I below and compared with the E.E.C. standards for potable water.

It is clear from Table I that the chemistry of the water pumped from the trial well changed slightly during the duration of the test pumping as is evident from the variation in sulphate, nitrate, calcium and bicarbonate values.

The chemistry of the Group Scheme well water is similar to that of the trial well with small differences in the calcium, magnesium and sulphate concentrations. The variation of the well water chemistry with time is also seen in the Group Scheme well with nitrate levels changing from a high of 9.7 mg/l to 3.2 mg/l between the Summers of 1980 and 1981. Whether this variation in nitrate levels is seasonal or affected by outside influences can only be determined by regular monitoring of the groundwater chemistry.

The relatively high levels of sodium and chloride in these groundwaters (Highland Spring, Na= 12.5, Cl = 15.6) is attributed to the proximity of Carrickbyrne to the sea with the result that precipitation in this region carries an unusually high concentration of these salts. The average chlorine level in Irish groundwater is 28 mg/l but this overall average is from

means for each aquifer ranging from 14.7 mg/l in the Castlecomer sandstone to 40 mg/l in the limestone dolomite aquifer of south Wexford.

Table I shows the waters tested from the Carrickbyrne area conform to the chemical standards of the E.E.C. directive on potable water quality. However, although the bacteriological analyses show no coliform bacteria present in the samples tested the colony count carried out on the sample of August 24th, gave a result that falls outside the E.E.C. standards.

Colony counts are not essential for assessing the safety of domestic water supplies. They are useful for indicating the efficiency of certain processes in water treatment and the cleanliness of the distribution system. They are also useful for determining the suitability of a water supply for the large-scale preparation of food and drink where, in order to avoid the risk of spoilage, the water should ideally contain few organisms of any kind. The high cell count recorded from the Carrickbyrne well may have been caused by soil or dust gaining access to the well during development.

VI. CONCLUSIONS AND RECOMMENDATIONS.

The results of the present drilling and testing programme show that the trial well at Carrickbyrne Hill is capable of a sustained yield of 109m³/day for 11 days and that the pumped water is of an exceptionally low mineralised character.

The water pumped from the trial well satisfies all but one of the E.E.C. standards for potable water but this divergence in the colony count may be related to the well development and so not a permanent feature. Changes in groundwater chemistry with time and pumping were noted in both the trial and Group Scheme wells especially in the sulphate and nitrate levels.

It is recommended that pumped samples be collected and analysed from both the trial and Group Scheme wells during late January and February of 1982 when groundwater levels are the highest, and the aquifer replenished by Winter recharge. These samples will show whether the low nitrate levels recorded in the last pair of analyses are annual low values and

whether the marginally high colony count is a permanent feature
of the Carrickbyrne trial well.
